P R E F A C E.

IN this work an attempt has been made to present in a somewhat concise form an account of the more important subjects comprised under the head of Practical Medicine, including also the Diseases Peculiar to Women.

In the selection of the subjects and the order of description, practical utility has been considered rather than completeness of detail, in the belief that such a work will probably be more often referred to with some immediate object in view than used for systematic reading.

All subjects properly belonging to Surgery have been excluded, but in some of the articles dealing with the Diseases of Women it has been necessary to give the details of the surgical procedures recommended.

Owing partly to the number of synonyms in common use, there is room for much divergence of view as to the most suitable headings under which to arrange the many subjects included in a Dictionary of Medicine. The rule here followed has been to place each description where it will most probably be looked for, and only in exceptional cases to group all the affections of an organ into one article—as, for example, “Spleen, Diseases of.”

For the reason already stated, and for facility of reference, the various sub-headings into which the description of a disease is usually divided are given in an order differing somewhat from that usually adopted, an account of the Symptoms, Course, Diagnosis, and Prognosis preceding that of the Pathology, Morbid Anatomy, and *Ætiology*. Each article concludes with the Treatment of the disease, and in order to avoid as far as possible a reproach frequently expressed, that on that subject comparatively little help is to be obtained from works on Medicine, the exact doses and combinations of the various drugs recommended

have in most cases been given, and it is hoped that this may add to the usefulness of the book to the practitioner.

A General Index, including a list of the articles, with cross-references, will be found at the beginning of the Dictionary.

The greater number of the unsigned articles are by Dr. John Abercrombie and the Editor.

The Editor desires to tender his thanks to all the contributors for their invaluable aid, and to many friends for most useful suggestions and advice.

LONDON, *July* 1890.

LIST OF CONTRIBUTORS.

ABERCROMBIE, JOHN, M.D., F.R.C.P.

Physician to Charing Cross Hospital, and Lecturer on Forensic Medicine ;
Assistant Physician, Hospital for Sick Children, Great Ormond Street.

ACLAND, THEODORE DYKE, M.D., F.R.C.P.

Assistant Physician to St. Thomas's Hospital ; Assistant Physician to the
Hospital for Consumption and Diseases of the Chest, Brompton.

BEALE, E. CLIFFORD, M.A., M.B., F.R.C.P.

Physician to the City of London Hospital for Diseases of the Chest, and to
the Great Northern Central Hospital.

BEEVOR, CHARLES EDWARD, M.D., F.R.C.P.

Physician to the National Hospital for the Paralysed and Epileptic ; Physician,
National Orthopædic Hospital ; Physician for Out-Patients, Great Northern
Central Hospital.

BURNET, ROBERT WILLIAM, M.D., M.R.C.P.

Physician to the Great Northern Central Hospital.

CARTER, WILLIAM, M.D., F.R.C.P.

Honorary Physician, Liverpool Royal Southern Hospital ; Professor of Materia
Medica, University College, Liverpool ; Consulting Physician, Liverpool
Eye and Ear Infirmary.

CAYLEY, WILLIAM, M.D., F.R.C.P.

Physician to the Middlesex Hospital and Lecturer on Medicine ; Physician to
the London Fever Hospital ; Consulting Physician to the North-Eastern
Hospital for Children.

COUPLAND, SIDNEY, M.D., F.R.C.P.

Physician to the Middlesex Hospital and Lecturer on Practical Medicine.

CROOKSHANK, EDGAR MARCH, M.B.

Professor of Bacteriology, King's College, London.

FINLAY, DAVID W., M.D., F.R.C.P.

Physician to the Middlesex Hospital and Lecturer on Forensic Medicine and
Public Health ; Physician to the Royal Hospital for Diseases of the Chest ;
Physician to the Scottish Hospital.

FOWLER, JAMES KINGSTON, M.A., M.D., F.R.C.P.

Senior Assistant Physician to the Middlesex Hospital, and Lecturer on Pathological Anatomy; Senior Assistant Physician to the Hospital for Consumption and Diseases of the Chest, Brompton.

FOX, THOMAS COLCOTT, M.B., M.R.C.P.

Physician for Diseases of the Skin, Westminster Hospital; Physician to Out-patients, Victoria Hospital for Children.

GAY, WILLIAM, M.D.

Late Clinical Assistant, Royal London Ophthalmic Hospital, Moorfields, and at the National Hospital for the Paralysed and Epileptic.

HADDEN, WALTER BAUGH, M.D., F.R.C.P.

Assistant Physician and Demonstrator of Morbid Anatomy to St. Thomas's Hospital; Assistant Physician to the Hospital for Sick Children, Great Ormond Street.

HALL, FRANCIS DE HAVILLAND, M.D., F.R.C.P.

Physician to Out-patients and in charge of Throat Department, Westminster Hospital, and Lecturer on Forensic Medicine; Physician to St. Mark's Hospital.

HERMAN, GEORGE ERNEST, M.B., F.R.C.P.

Obstetric Physician to the London Hospital and Lecturer on Midwifery.

HIME, THOMAS WHITESIDE, M.B.

Honorary Medical Officer, Sheffield Hospital for Women; Medical Officer of Health for Bradford, Yorkshire.

HOPWOOD, EDGAR OSWALD, M.D., B.A.

Resident Medical Officer to the London Fever Hospital.

HORSLEY, VICTOR, F.R.S., F.R.C.S., M.B., B.S.

Professor of Pathology, University College, London; Professor Superintendent of the Brown Institution; Assistant Surgeon to University College Hospital; Surgeon to the National Hospital for the Paralysed and Epileptic.

HUDSON, CHARLES E. L. B., F.R.C.S.

Warden of the Middlesex Hospital College and Surgical Registrar to the Hospital.

KIDD, PERCY, M.A., M.D., F.R.C.P.

Assistant Physician to the London Hospital; Assistant Physician and Pathologist to the Hospital for Consumption and Diseases of the Chest, Brompton.

LANG, WILLIAM, F.R.C.S.

Ophthalmic Surgeon to the Middlesex Hospital and Lecturer on Ophthalmic Surgery; Surgeon to the Royal London Ophthalmic Hospital, Moorfields.

LUFF, ARTHUR PEARSON, M.B., B.Sc.

Assistant Physician to St. Mary's Hospital, and Lecturer on Medical Jurisprudence and Toxicology; Assistant Physician to the North-West London Hospital.

MAC ALISTER DONALD, M.A., M.D., F.R.C.P.

Physician to Addenbrooke's Hospital, Cambridge; Member of the General Medical Council.

MAGUIRE, ROBERT, M.D., F.R.C.P.

Physician to Out-patients, St. Mary's Hospital, and Joint Lecturer on Pathology; Assistant Physician to the Hospital for Consumption and Diseases of the Chest, Brompton.

MONEY, ANGEL, M.D., F.R.C.P.

Assistant Physician to University College Hospital, and Assistant Professor of Clinical Medicine; Assistant Physician to the Hospital for Sick Children, Great Ormond Street.

MOTT, FREDK. WALKER, M.D., M.R.C.P.

Assistant Physician to Charing Cross Hospital, and Lecturer on Physiology.

MURRAY, HERBERT MONTAGUE, M.D., M.R.C.P.

Physician to the Foundling Hospital; Assistant Physician and Physician in charge of the Electrical Department, Charing Cross Hospital, Lecturer on Pathology and Morbid Anatomy, and Joint Lecturer on Practical Medicine.

MYERS, ARTHUR THOS., M.A., M.D., M.R.C.P.

Physician to the Belgrave Hospital for Children.

OWEN, ISAMBARD, M.A., M.D., F.R.C.P.

Assistant Physician to St. George's Hospital, Lecturer on Medical Jurisprudence.

PASTEUR, WILLIAM, M.D., M.R.C.P.

Assistant Physician to the Middlesex Hospital; Physician to the North-Eastern Hospital for Children.

PENROSE, FRANCIS GEORGE, M.D., M.R.C.P.

Assistant Physician to St. George's Hospital.

PRINGLE, JOHN JAMES, M.B., M.R.C.P.

Assistant Physician and Physician to the Skin Department, Middlesex Hospital.

REVINGTON, GEORGE THOS., M.A., M.D.

Assistant Medical Officer, County Asylum, Prestwich, Manchester.

SAUNDBY, ROBERT, M.D., F.R.C.P.

Physician to the Birmingham General Hospital; Consulting Physician to the Birmingham Eye Hospital, and to the Hospital for Women.

SHELLY, CHARLES EDWD., M.A., M.D.

Hon. Med. Officer to the Hertford General Infirmary; Medical Officer to Haileybury College.

SMITH, R. PERCY, M.D., F.R.C.P.

Resident Physician and Medical Superintendent, Bethlem Royal Hospital.

STEAVENSON, WM. EDWARD, M.D., M.R.C.P.

In charge of the Electrical Department, St. Bartholomew's Hospital; Physician to the Alexandra Hospital for Children, and Grosvenor Hospital for Women and Children; Physician for Diseases of Women and Children, St. George's and St. James's Dispensary.

SUTTON, J. BLAND, F.R.C.S.

Assistant Surgeon to the Middlesex Hospital, Lecturer on Comparative Anatomy, and Senior Demonstrator of Anatomy; Sir Erasmus Wilson Lecturer, and late Hunterian Professor, R.C.S. England.

WHITE, WM. HALE, M.D., F.R.C.P.

Physician to Guy's Hospital and Lecturer on Materia Medica and Therapeutics.

WIGLESWORTH, JOSEPH, M.D.

Assistant Medical Officer, County Asylum, Rainhill, Lancashire.

WILLIAMS, DAWSON, M.D., M.R.C.P.

Assistant Physician to the East London Hospital for Children.

GENERAL INDEX.

DICTIONARY

OF

PRACTICAL MEDICINE.

A

ABDOMINAL TUMOURS, Diagnosis of.—In the clinical sense, the term “abdominal tumour” is of very wide significance. It comprises any condition that causes general or partial enlargement of the belly, and is by no means limited to the class of new growths or cysts. The diagnosis, then, of the nature of an abdominal swelling, intumescence, or tumour embraces a large number of questions. It is, moreover, often a matter of difficulty to make such diagnosis by the methods of physical examination available. So great is this difficulty that it has even been said that nothing short of actual inspection after opening the abdominal cavity can lead to a correct diagnosis—a statement certainly true of many cases, but not of all. The main difficulties encountered in these cases by the clinical observer are due to the following circumstances:—(1) The great variation in the form and size of the abdomen in normal conditions. (2) Thickness of abdominal walls from excessive accumulation of subcutaneous fat, and rigidity of the wall from contraction of its muscles. (3) The simulation of true tumours by transient states known as “phantom” tumours. (4) The close proximity of some of the organs to one another, and the variable limits of the hollow viscera, rendering it difficult to localize the tumour. (5) The fact already mentioned of the very great variety of conditions that on abdominal inspection, palpation and percussion, yield the signs of a tumour.

There are at least two ways of dealing with this wide subject. We may either discuss *seriatim* the various abnormal swellings according to their nature and origin, or we may take a more clinical view and deal in turn with swellings of the whole of the abdomen, and then of those of its separate regions. The plan here pursued will be mainly the anatomical one; but, of course, reference will be made to the regional classification. Moreover, although it might be more scientific to group the conditions according to their pathological affinities, it is obvious that plan would involve much repetition, and might not serve the object in view—viz., the differential diagnosis in the living subject. We shall therefore speak in turn of conditions coming under the head of abdominal tumour as arising in connection with (1) the abdominal parietes, (2) the peritoneum and sub-peritoneal tissue, (3) the several abdominal and pelvic viscera, (4) the pelvic bones, and add a few words concerning (5) abdominal aneurysm and (6) phantom tumours. For fuller details of any of these morbid conditions reference must be made to articles specially dealing with them.

I. Tumours, &c., arising in the Abdominal Wall.—These often closely simulate tumours lodged within the abdominal cavity. We may mention among these swellings those produced by extravasation of blood beneath the skin, or between the muscles, or within the sheath of the rectus. Such a *hematoma*

may arise from an injury to the belly, as a blow or sudden violent strain, causing rupture of muscle fibres; or from the spontaneous rupture of a muscle, preferably the rectus, which has undergone Zenker's degeneration. This peculiar form of degeneration is liable to occur in cases of continued or high fever. It is not uncommon in typhoid fever, and the writer has known an instance of rupture of both recti, during acute pneumonia, from the patient leaping out of bed in a fit of delirium. The muscular fibres are rendered extremely brittle by this change, and hence readily give way if the muscle be forcibly contracted. The occurrence of this lesion and the resulting hæmorrhage may not be suspected during life, but occasionally it is declared by the appearance of a firm, defined, and tender swelling in the abdominal wall, on one or other side of the middle line, and generally below the umbilicus. There is mostly no discoloration of skin, the effusion being confined within the dense fascial sheath. If the case do not end fatally from the fever, the swelling will be observed to become softer, and will probably suppurate. In other cases there may be a history of injury to aid in diagnosis. Blood may also be effused into the abdominal parietes by the rupture of an abdominal aneurysm when this takes place posteriorly and allows of the gradual escape of blood into the tissues. In such a case of "diffuse aneurysm" there may appear a swelling in the flank which will gradually extend forwards, and, both to palpation and percussion, give the signs of a tumour. Should the hæmorrhage cease, the anterior margin of the swelling will become more defined, whilst here and there its surface may become soft and fluctuating. The appearance of such a tumour may precede by some days the final rupture.

In connection with this subject of *infiltrations* in the abdominal wall may be mentioned a condition not infrequently met with in cases of tubercular peritonitis in children. This is a peculiar induration, confined to various parts of the wall, which, on palpation, feels hard and rigid, suggestive of contracted muscles. But the hardness remains when the muscles are relaxed by an anæsthetic. The condition cannot be mistaken for scleroderma, for the induration is obviously deeper than the skin. It is possibly due to some inflammatory effusion into the subperitoneal or other tissues of the abdominal wall; it may indeed gradually disappear, as in a case known to the writer, where

the area of induration at first corresponded with that of the external oblique muscle.

Abscesses may arise in the abdominal wall from causes similar to those producing hæmatomata. Thus, one of the commonest is as a sequel of rupture or inflammation of a muscle due to violent and sudden effort or strain; and here again the rectus is the muscle most commonly involved. Or a violent blow on the surface may lead to localized inflammation and suppuration. As distinguished from such primary abscesses, the parietes may be invaded by the extension to the surface of deeply seated abscesses connected with caries of spine, rib, or pelvic bones, or from inflammation around the cæcum, kidney, gall-bladder, or other viscus (*e.g.*, fæcal abscess), or as the result of pelvic cellulitis, &c. In all cases of abscess in the wall its possible origin in deeper parts must therefore be borne in mind. It is not always easy to determine that an abscess is limited to the wall, especially as it is often beneath the superficial fascia or muscles. Such an abscess forms generally a smooth, rounded swelling, elastic, mostly tender, frequently painful, although if it be quiescent this latter symptom may be absent. Fluctuation can generally, but not invariably, be obtained. If the abscess be extending, then, besides hectic and other signs of active suppuration, there will probably be some redness and œdema of skin over the swelling. In every doubtful case the abdomen should be carefully palpated under chloroform, no more forcible manipulation being used than if the patient were not anæsthetized. The diagnosis may only be reached by a process of exclusion, for such an abscess has been mistaken for hydatid, or intussusception, even for aneurysm when seated over the aorta or an iliac artery, the pulsation of the vessel being transmitted through the abscess. In the last-named case it is well to palpate the swelling when the patient is in the knee-elbow posture, when the pulsation will be found to cease. To distinguish it from a solid tumour in the wall it may be necessary to make an exploratory puncture with a grooved needle or the aspirator. The fact that the abscess contains gas does not necessarily mean that it is directly or indirectly connected with stomach or bowel, for there is no doubt that the contents of a deep-seated abscess in the wall, in contact with intestines, may putrefy. It is needless to point out the risk of leaving an abscess in this

situation unopened—viz., the liability to rupture into the peritoneal cavity.

Cases of *simple cyst* in the abdominal wall have been described, and require mention, although the condition is a very rare one. It is analogous to the congenital cystic hygromata occasionally met with in the neck and elsewhere. Such cysts may attain a large size, as in one mentioned by Mr. T. Smith in the course of a discussion at the Clinical Society in 1880. It was the case of a child, whose belly was so distended and round that it "looked like a large gooseberry," and as the child was in such good health Mr. Smith postponed operation; but no surgical interference was needed, for one day after dinner the boy, in falling off a high chair, "burst himself," and forthwith the large fluctuating swelling entirely disappeared. A somewhat similar case was in the Middlesex Hospital in 1874. A boy aged six years presented a fluctuating swelling in the epigastrium, which, on aspiration, yielded some ochrey fluid. In a few months the fluid re-accumulated, and was again withdrawn. The aspiration had to be once more repeated, but all further need for evacuation was obviated by the boy falling down when running in the garden, and presumably rupturing the cyst, which ceased from that time to be evident. The cyst in this case was probably of hæmorrhagic origin, from the character of the fluid, and the history of a fall from a height two years before preceding the appearance of the swelling.

Besides the forms of new growth arising in the skin or subcutaneous tissue (*molluscum fibrosum*, *lipoma*, etc.) the abdominal wall may be the seat of *tumours* starting from the fasciæ or embedded in the substance of the muscles. Here again the rectus and its sheath are the structures most frequently involved. *Gummata* may occur in the muscle; *fibromata*, *myxomata*, or *sarcomata* in the fascia. The discussion of the several characters of such tumours does not come within the scope of this work; they are dealt with in surgical treatises. But such cases are of interest from the manner in which they simulate tumours within the abdominal cavity. The points to be noted in differentiating them are the following:—(1) The relation of the tumour to the abdominal muscles as determined by causing the patient to contract the muscle, and observing whether the tumour becomes more or less apparent during the contraction. Of course, if the growth in the wall be

beneath the muscle, it will be concealed by the contracted muscle, and the test is therefore not absolutely certain to exclude an intra-abdominal growth. (2) By palpation when the patient is on his hands and knees the parietal growth becomes more easily felt and its freedom from deep connections may be ascertained. (3) In many cases examination has to be made under chloroform.

II. Tumours, &c., connected with the Peritoneum and Sub-peritoneal Tissues.—There are many conditions, inflammatory and neoplastic, involving the peritoneum or its subjacent connective tissue, which fall under the head of abdominal tumours. But inasmuch as the serous sac lines the whole of the cavity, there are also certain of its lesions which produce a general enlargement of the abdomen. Such conditions are those in which there is effusion of fluid or gas into the peritoneal sac, and they may be first briefly referred to.

Under the general term *ascites*, it is usual to include all serous effusions into the peritoneum, dropsical or inflammatory. The former occur in cases of obstructed portal circulation, as in cirrhosis of the liver, or as part of a general cardiac dropsy, or of renal dropsy; the latter are met with in some cases of chronic peritonitis, and especially in tubercular or malignant disease of the peritoneum, the effusion in some of the latter cases being perhaps partly due to pressure on the portal vein by enlarged glands. There is seldom much difficulty in the diagnosis of ascites, except where the effusion is scanty or is contained in loculi formed by adhesions at various points. In a well-marked case the belly is uniformly enlarged, the flanks full, there is free fluctuation to be obtained across the abdomen, and, on percussion, there is dulness in each flank and over the lower half or more of the anterior wall when the patient is in the recumbent position, the dulness shifting with the position of the body. In cases when the intestines are distended with flatus and fluid feces, this shifting dulness may be obtained without there being any fluid in the peritoneal sac; but the writer only knows of two cases of this kind, and it may be safely said that the sign of shifting dulness is almost pathognomonic of ascites. It is less easy to be certain of the peritoneal origin of a loculated or encysted collection of fluid, since, in that case, the flank may be resonant and the area of dulness may not alter with the position of the body.

The condition most likely to be mistaken for ascites is a large unilocular ovarian cyst (ovarian dropsy). The shape of the abdomen, the resonant note in the flanks, and the history of the case will aid in the differentiation (*vide infra*).

In cases of perforation of the stomach or intestine the belly may become distended by the escape of *gas* into the peritoneum. This may almost invariably be distinguished from tympanites due to extreme flatulent distension of the intestines by the *entire* disappearance of the hepatic dulness caused by the gas collecting between the liver and parietes. It is sometimes of great importance, with regard to treatment, to determine the fact of perforation, and this sign may be fully relied on.

TUBERCULAR DISEASE OF THE PERITONEUM is characterized, so far as abdominal examination goes, by various signs. In many cases there is nothing to be made out on palpation. There is generally some fluid effusion, sometimes in considerable amount, but, owing to matting of intestines, the fluid may be collected in different places, and thus the characteristic signs of ascites may not be present. However, in several cases there is typical ascites. The matting together of the intestines is often indicated in the emaciated subjects of this affection by the detection on palpation of irregular, but resonant, tumours in various parts, or by the occurrence of ridges and masses of irregular shape, especially in the umbilical region, when the omentum is infiltrated. The presence of such tumours aids the diagnosis, but more value attaches to collateral evidence—*e.g.*, the age of the patient, family predisposition to tubercle, remittent pyrexia, pain and tenderness in the abdomen, diarrhoea (often absent), and in many cases (but by no means in all) the concomitance of signs of pulmonary phthisis.

MALIGNANT DISEASE OF THE PERITONEUM is usually secondary to cancer of one of the abdominal or pelvic organs, but the disease may not have attracted attention until the peritoneum has become involved, and in some cases the primary cancer is quite latent. As with tubercle, so here the main signs may be those of ascites, which can be of excessive amount, necessitating paracentesis. In that event the character of the fluid that is withdrawn is suggestive, for in peritoneal cancer it is often blood-stained, and microscopical examination may reveal in it great abundance of epithelioid cell-forms. After paracentesis, palpation

may detect masses and irregular tumours in the abdomen. The history of the case is of course of considerable importance in diagnosis, which mainly rests between this disease and cirrhosis of the liver. There are two forms of abdominal cancer in which the signs are generally fairly obvious. These are cancer of the omentum and colloid cancer of the peritoneum. When the omentum is affected it becomes thickened and contracted, forming a large lobulated mass with irregular margins situated in the lower epigastric and the umbilical regions. It is well defined, dull on light percussion, and generally separated from the hepatic area by a strip of resonance. The co-existence of such a tumour, in an elderly subject, with ascites (and perhaps jaundice also) and a history of progressive emaciation and pain would justify the diagnosis of omental cancer. On the other hand, the omentum may not be retracted as stated, but infiltrated in its whole extent so as to present a wide area of dulness reaching in the median line from xiphoid to pubes; and in such a case the diagnosis from malignant ovarian disease is very difficult. As regards colloid cancer, the greater part of the belly may be occupied by irregular masses separated by areas of resonance, the masses being more or less nodular and even distinctly elastic to the touch.

Tumours arising in the *mesentery* and in the *retro-peritoneal glands* may be found on palpation to be rounded, lobulated, but may not yield dulness, being overlaid by the intestine. The retro-peritoneal growths are moreover fixed, and cannot be moved by pressure or influenced by the movements of the diaphragm. In their case the diagnosis has to be made from renal tumours (*q.v.*) and from growths connected with the lumbar spine.

Passing now to consider inflammatory conditions of limited extent and involving the sub-peritoneal tissue as well as the serous membrane itself, the most notable and common is that described under the head of *peri-typilitis*. This condition, which arises in the vast majority of cases from ulcerative perforation of the vermiform appendix, is mostly a localized peritonitis or peritoneal abscess, so that what applies to it may, *mutatis mutandis*, be applied to such abscesses in general. For it is not every case of perforated appendix that leads to general and fatal peritonitis. Peri-typilitis is characterized by pain and tenderness in the right iliac fossa, where may be felt an area of resistance, and often a fairly well defined

swelling in the same region, which yields a dull note on percussion. In cases that proceed to suppuration, further signs appear, as redness and inflammatory œdema of the skin, followed by bogginess, and perhaps the crepitation of subcutaneous emphysema. In other cases the abscess, instead of pointing externally, will burrow down into the pelvis and ultimately open into the rectum or bladder, or else (as in a case recently under the writer's care) it will make its way in the deep layers of the abdominal wall even as high as the diaphragm. As to other abdominal abscesses, they may be found in almost any part of the belly, being, however, mostly the result of perforation of intestine, stomach, or gall-bladder, especially where such perforation has been so gradual as to have given time for the formation of peritonitic adhesions between adjacent coils of intestine, and thus to limit the focus of suppuration. A peri-typhlitic abscess may be confounded with a faecal tumour or a tumour of the cæcum, but the history of the case, the pyrexia, and the evidence of local inflammation will generally enable a correct diagnosis to be formed. It is only where a peri-typhlitis persists for a long time without resolving or suppurating that a doubt may arise as to the correctness of the original diagnosis. Sometimes a peri-nephritic abscess on the right side may invade the iliac region, but its extension from the loin and the history of renal symptoms suffice to distinguish it.

Before leaving this part of the subject it may be well to mention the fact that a *pelvic hæmatocele* or a *pelvic cellulitis* may extend beyond the limits of the true pelvis, and come to occupy the iliac fossa. In such cases, apart from the history, the result of vaginal examination will furnish facts for a diagnosis, by permitting of the detection of the swelling in Douglas's fossa and the displacement or fixation of the uterus.

III. Tumours, &c., connected with the Abdominal Viscera.—I. STOMACH.

—A *dilated stomach* may cause a marked prominence in the epigastric and left hypochondriac regions, so that the outline of the greater curvature of the viscus can be readily seen. In chronic dilatation the organ often assumes a lower position than normal, and the epigastric region may then be flat instead of rounded. On percussion a full tympanitic note is yielded by the swelling, whilst, if there be much fluid contents, a marked splashing can be produced by suddenly palpating it.

Not every *new growth of the stomach* is

to be detected by physical exploration; its presence can often only be inferred by the symptoms and course of the disease. But the existence of an obvious tumour materially favours the diagnosis. Thus, cancer of the cardiac orifice is beyond the sphere of external observation, and its symptoms are those of œsophageal obstruction; cancer of the pylorus can generally be detected by palpation, and it is accompanied by gastric dilatation. In either case there is extreme emaciation, rendering palpation easy. Scirrhus, the commonest form of pyloric cancer, may be felt during life as a hard nodule in the right of the epigastrium or the contiguous part of the hypochondrium. It is fixed, and indeed is frequently adherent to neighbouring organs, as liver or pancreas, being sometimes quite concealed by the former. If the new growth, cancerous or not, be seated in the anterior wall of the viscus, or near the greater curvature, it is far more mobile, provided that it has not progressed so far as to have caused the stomach to become adherent to the abdominal wall. Indeed, such a tumour may alter its relative position from time to time according to the varying state of distension of the viscus. It is usually held to be distinctive of gastric tumours, as contrasted with those of the liver (left lobe), that they are but little, if at all, influenced by the movements of the diaphragm. This is not absolutely the case, for certainly there may be some descent of such a tumour with inspiration, although the movement may not be so great as that of the liver itself. It is impossible to distinguish a gastric from a hepatic tumour if the former be adherent to the liver, for in that case the strip of resonancé, which otherwise may occur between the tumour and the area of liver dulness, does not exist. The tumour in the gastric wall varies in its degree of dulness with the distension of the stomach.

In not a few cases of simple *pyloric stricture* or *chronic ulcer* a nodular tumour may be felt, simulating a new growth, and a correct diagnosis can only be based upon the long duration of the symptoms, since in either case there is marked cachexia with general wasting. In the very emaciated subject of such disease even the normal pancreas may be mistaken on palpation for a growth in the stomach.

2. **INTESTINE** (omitting Hernial tumours).—*Flatulent distension* of the intestines gives rise to more or less general enlargement of the abdomen; it

is more marked in the colon as a rule; but in cases where the small intestines alone are distended, as in obstruction at the cæcum or above, then the flanks will appear flattened in comparison with the great prominence of the rest of the belly. In acute peritonitis the whole of the bowels may be distended, and the tense abdominal wall give a tympanitic note on percussion.

Apart from this condition there are three widely different causes of intestinal trouble productive of definite localized swellings or tumours. The first of these is *faecal accumulation*. In every case of suspected abdominal tumour the possibility of its being a mere faecal tumour must be borne in mind; hence it is always advisable to thoroughly clear out the bowels before arriving at a conclusion as to any abdominal tumour. A faecal tumour consists, then, in the lodgment in the large intestine of a mass of inspissated faeces. It may occur in the cæcum, giving rise to a swelling which has to be distinguished from the graver condition of typhlitis; the tumour is well defined, and not usually tender; it may be indented to a certain extent by the finger. Or it may be formed in any part of the colon, of which the sacculi, especially if the gut be dilated, afford convenient receptacles for such a lodgment of faeces without interfering with the daily evacuation. The sigmoid flexure is a favourite seat, and it must be remembered that this portion of bowel is prone to great variation in its position, according to the length of the meso-sigmoid; sometimes it lies on the right of the middle line. Similarly, the transverse colon may be considerably displaced, forming quite a U-shaped curve with the convexity approaching the pubes. Such changes in the position of the colon account for the appearance of these faecal tumours in various parts of the abdomen not occupied by the large bowel when normally situated. The tumour may be considerably below the umbilicus, and yet be formed in the transverse colon. A faecal tumour is easily grasped, dull on percussion, and sometimes has a manifestly doughy consistence, but the diagnosis requires for its confirmation the frequent administration of large enemata. Even then it may take some time to reduce its size or effect its dislodgment, and in some cases its gradual onward passage along the colon can be traced on palpation from day to day. The conditions for which such a tumour is liable to be mistaken are intussusception or an intestinal growth.

The tumour of *intussusception*, when present, is of characteristic shape, from the fact that it is formed by the invagination of a segment of gut into the portion just beyond it. Although no part of the bowel is exempt from such an occurrence, yet the most common variety is that in which the invagination begins at the ileo-cæcal valve, the ileum and cæcum being intussuscepted into the colon. Hence the usual site for the smooth, sausage-shaped tumour to occupy is either the right lumbar region or transversely across the belly in the upper part of the umbilical region. Yet in some cases it may even be formed on the left side, and the intussuscepted portion be felt *per rectum*. The diagnosis does not depend merely upon the presence of the tumour, but is largely based upon the history of the attack and the occurrence of symptoms of obstruction, of melæna, &c. It is in cases of so-called chronic intussusception that most difficulty arises, for in such cases the collateral evidence may be wanting to confirm the view taken as to the nature of the tumour (*see* **INTESTINAL OBSTRUCTION**).

New growths of the intestine are not very common. Those that are least rare seldom attain a size sufficient to render them palpable, or else they are seated in regions beyond the reach of the hand. Thus the commonest are the limited epitheliomata that are met with chiefly in the large intestine at the several flexures, where they form annular ulcers, and are a main cause of chronic obstruction. The same kind of malignant growth may occur in the cæcum, where also other varieties of tumour are met with; the diagnosis has to be made, not only from faecal tumour or intussusception, but also from peri-typhlitis; here the history of the case is quite as useful in differentiation as the determination of the presence of a swelling. In malignant disease the existence of enlarged glands or of œdema of the lower limb may assist in diagnosis. Much more rarely do we meet with cases of tumour (simple or malignant) in the small intestine. Such may be detected on palpation in any of the abdominal regions below the umbilicus, rarely above that level.

3. **LIVER AND GALL-BLADDER.**—The general characters of a tumour connected with the liver consist in its being situated in the right hypochondrium or epigastrium, in its accompanying the liver in its movements during the act of respiration, in the dulness obtained over the swelling being conterminous with that of

the liver, and in some cases—perhaps a minority—in its association with jaundice. An enlarged liver forms the most common variety of abdominal tumour.

Conditions of *chronic uniform enlargement*, such as that due to chronic congestion of cardiac disease, or to hypertrophic cirrhosis, fatty infiltration, waxy degeneration, or leukæmic infiltration, need merely be mentioned. They are fully described elsewhere, and the signs elicited by palpation and percussion are plain. The conditions with which they may be confounded are not those of other abdominal tumours, but rather with downward displacement of the organ itself.

There are also conditions of the liver which depend on causes productive of *distortion* of the organ, and produce swellings that may be mistaken for true tumours. The liver is sometimes remarkably deformed by the practice of habitual tight-lacing—a practice not confined to any one grade of the social scale—so that in extreme cases a considerable portion of the organ may be felt below the ribs as a hard, resisting, somewhat rounded tumour. Again, in syphilitic peri-hepatitis the liver may be greatly distorted, and present on its surface more or less large bosses which might be mistaken for malignant tumours.

Of conditions giving rise to localized swellings mention may first be made of *cysts and abscesses*. These fluid tumours are smooth, elastic, and, if not too deeply seated in the substance of the organ, fluctuating. It is well to remember that even a fatty liver, or some other condition (as leukæmia), whilst involving the whole organ, may by some local bulging give rise to an elastic swelling, and therefore a diagnosis may not be possible unless the swelling has been explored by a grooved needle or fine trocar. *Simple cysts* are too rare to require detailed notice; prior to exploration, they will probably be taken for hydatid cysts. The characters of *hydatid tumour* are only manifest when the cyst projects above the surface of the liver; but in cases where the hydatid is lodged deeply in the substance of the organ, the latter is more enlarged as a whole, or rather there is disproportionate size of the lobe involved. In some cases the cyst only just presents on the surface, and then it gives the impression of a solid, nodular growth. But, in the more ordinary event, it forms a smooth, elastic, round, or oval swelling, which, both by palpation and percussion, can be proved to be intimately connected

with the liver. The so-called “hydatid fremitus” is a modified sense of fluctuation, sometimes obtained by placing the palm of one hand upon the tumour, and striking the dorsum with the fingers of the other hand; a tremor or thrill is thereby perceived, this being doubtless due to the physical conditions of a cyst containing fluid, and provided with a tense, elastic wall. An exploratory puncture is necessary to establish the diagnosis, when the characteristic clear, thin, non-albuminous fluid will be withdrawn, containing, perhaps, scolices, hooklets, or shreds of laminated membrane. If supuration have taken place, the presence of pus is, of course, at once perceived. A degenerate and shrivelled hydatid is clinically indistinguishable from a solid growth (for further details, *see* HYDATID).

A *solitary abscess* of the liver may point below the ribs and appear in the hypochondrium as a prominent swelling, through which fluctuation may readily be obtained. The history of the case and the concomitant symptoms are of importance, and aspiration should be employed as an aid to diagnosis. In many cases, however, the abscess does not so project, but declares its presence by causing enlargement of the liver and other signs, the consideration of which does not come within the scope of this article.

The forms of *solid tumour* met with in the liver include syphilitic gummata and various kinds of malignant growth, the latter being mostly secondary to disease of other parts. Gummata seldom attain any large size; they may project from the surface of one or other lobe as a hard nodule, which, from its persistence without much change in size or affection of the general nutrition, is to be distinguished from a cancerous growth. Under anti-syphilitic treatment the tumour may entirely disappear. Cancer of the liver is not only mostly secondary, but also generally multiple. The organ is greatly enlarged, and numerous rounded, bossy prominences are to be felt on its surface; or—and this is more common in cases of primary cancer—there is one large firm tumour bulging from the hepatic lobe. As a rule, there is not much difficulty in the diagnosis, especially when, as often is the case, jaundice and ascites are present. In the latter event, if the effusion be not extreme, the liver can be palpated through the layer of fluid, which can be felt to be displaced. But many other kinds of abdominal tumour have been mistaken for hepatic growths—*e.g.*, fecal

tumour in the transverse colon, tumour of the right adrenal, or right kidney, or growths arising in the peri-renal tissues, or tumours of the stomach. In some of these cases a diagnosis is hardly to be made by physical examination alone.

Tumours formed by the *enlarged gall-bladder* or by new growths of this viscus deserve separate mention. In consequence of obliteration of the cystic duct from impacted calculus, or stricture following ulceration, or compression from without upon this duct or the common bile duct, the gall-bladder may become greatly distended and appear beneath the margin of the liver as a pyriform or oval swelling in the situation of the viscus. Such a tumour is tense, smooth, and it may be possible to detect fluctuation in it.

The undistended gall-bladder is not palpable, so that if the viscus can be felt it must be enlarged. In such a case there may or may not be a history pointing to gall-stone or evidence of malignant disease. The smooth ovoidal tumour in this situation is quite characteristic, and can hardly be mistaken for any other form of tumour. The gall-bladder may also be the seat of primary cancer, and in that case a firm, rounded tumour, dull on percussion, is to be found projecting below the rest of the lower margin of the right hepatic lobe. By its position alone can its true nature be surmised, for in all essential characters it resembles a tumour of the liver. In some cases of malignant disease of the gall-bladder there is a history of previous attacks of biliary colic.

4. **PANCREAS.**—Owing to its somewhat deep situation in the abdomen behind the stomach, an enlarged pancreas is not always palpable, whilst for the same reason the percussion note over it is resonant. In cases where the stomach is contracted and empty, however, even an unenlarged pancreas may be felt, especially at its head, its situation being to the right of the middle line at the upper part of the umbilical region. The only form of tumour that is likely to be met with is cancer of the organ, a disease which generally attacks the head of the pancreas; its hardness and fixity are distinguishing features; whilst, from its contiguity to the common bile duct, the growth generally is accompanied by obstructive jaundice. The tumours likely to be confounded with pancreatic are growths in the omentum or stomach; and if, as often happens, such growths have become adherent to adjacent structures,

and are consequently no longer mobile, a positive diagnosis may be impossible. The occurrence of fat in the stools is said to indicate pancreatic disease, and recently attention has been drawn to the fact that the stools may become clay-coloured in such cases, even although there may be no jaundice.

5. **SPLEEN.**—An enlarged spleen is for the most part readily detected by abdominal palpation. It is felt as a smooth tumour passing forwards from beneath the ribs into the left hypochondrium; its margin may be somewhat sharp or rounded, and the characteristic notch in its anterior border can often be detected. Again, on percussion the abdominal swelling is found to be continuous with the area of splenic dulness in the lower axillary region, whilst the fact that the tumour is superficial to the colon affords further proof of its nature. Moreover, the spleen accompanies the diaphragm in its movements. The conditions causing enlargement of this organ include the swelling met with in typhoid and septic fevers, in malaria, from chronic congestion, waxy disease, leukokythæmia, &c. (*see DIS. OF SPLEEN*). Localized tumours are not common; they include hydatid cysts and malignant growths. Occasionally the spleen is movable, but it retains its characteristic shape, and can be pushed upwards and backwards into its normal position.

6. **KIDNEY.**—The kidneys are, in moderately thin subjects, easily palpated, the surest way being to support the organ by means of one hand placed in the flank, whilst palpating the anterior margin and surface with the other hand. An enlarged kidney or a renal tumour may be diagnosed as such if the following characters are present:—The surface and margin are smooth, the latter being rounded and thick. There is resonance over the anterior half of the tumour, owing to the relation borne to the kidney by the colon. Then such a tumour is unaffected by the movements of respiration, and, indeed, except in the case of a movable kidney, its situation is fixed. These points may serve to distinguish a renal from a splenic tumour. The occurrence of urinary symptoms of course would materially aid in the differential diagnosis, but such symptoms are often absent.

Hypertrophy of one kidney—which may occur as compensatory to atrophy or congenital absence of its fellow-organ—may render the kidney more readily palpable than it normally is, but the

actual diagnosis of this condition is seldom determined during life.

One or both kidneys may be *movable*—that is, from the laxity of the fatty tissue around the organ, or the wasting of this tissue, the kidney may become gradually capable of being displaced from its bed according to the position of the patient, or it may readily be so displaced by manipulation. The majority of instances are met with in women who have borne many children, and in whom, therefore, the abdominal walls are remarkably lax. The practice of tight-lacing has by some been held responsible for displacement of the kidney, especially the right one. The right kidney is more frequently mobile than the left, but in the same subject both may present this abnormality. Sometimes the condition gives rise to considerable discomfort or inexplicable pains. The diagnosis rests upon the following points:—(1) The detection of a smooth, firm tumour in the abdomen, of the shape and size of a kidney, and capable of being moved between the hands; (2) although lying, perhaps, close to the middle line of the body, it may be pushed backwards into the loin; (3) when the patient is lying prone, a distinct hollow is to be seen in the lumbar region, where the kidney ought to lodge, and a resonant note may be found to have replaced the normal area of kidney dulness; (4) the patient will experience a peculiar sensation when the organ is compressed by the hand. The only other mobile tumours likely to be mistaken for a movable kidney are fibroid tumours of the uterus, which are sub-peritoneal, are furnished with a long pedicle, and are of the size of the kidney. Ovarian tumours under similar conditions may also simulate movable kidney. Nevertheless, the latter has sometimes been mistaken for a fecal tumour, or a tumour of the liver, gall-bladder, &c.

When, in consequence of obstruction to the outflow of urine, the pelvis and calyces of a kidney become dilated and distended with urine (*hydro-nephrosis*) or pus (*pyo-nephrosis*), the condition is characterized clinically by the appearance in the lumbar region of the abdomen of a prominent swelling, which may extend as far forwards as the umbilicus, or even beyond it. The tumour is smooth, elastic, or fluctuating, rounded, and fixed; perhaps it is dull over its whole extent, or anteriorly the resonance of the intestine may limit the percussion area. In some such cases additional evidence of its true nature may be afforded by the tumour

alternately increasing and dwindling in size, the latter event being accompanied by an unusual increase in the flow of urine or in the amount of pus that is discharged with the urine (intermitting hydro- or pyo-nephrosis).

Although widely differing in their pathological characters and also in their clinical history, there is much resemblance, so far as regards the characters of the tumour to which they respectively give rise, between the enlargement produced by *tubercular disease* of the kidney and that caused by *calculous pyelitis*. In either case a large tumour is to be felt in the loin, where the patient generally complains of pain of a constant, aching character. There may be manifest fulness in the loin, and the tumour may seem to be lobulated; it probably also appears to be solid, for although the kidney is really reduced more or less to the condition of a chambered sac containing pus, yet, owing to the thickness of the chronically inflamed capsule, no evidence of the presence of fluid contents may be obtained. The peri-nephritis that so commonly results from these forms of suppurative disease of the kidney may itself pass on to suppuration, and an abscess be formed in the region of the tumour, or burrow in the abdominal wall, where its presence may be recognized. As to the differential diagnosis between these two diseases, it must suffice here to point out that calculous pyelitis may be suspected if there has been a history of previous attacks of renal colic and hæmaturia; whilst in cases of tubercular kidney the symptom of pyuria (which is common to both conditions) may be associated with evidence of tubercle in other organs, as the lungs or intestines, or, if the patient be a male, in the other parts of the genito-urinary tract—*e.g.*, the vesiculæ seminales, spermatic cord, testes, bladder, or prostate. In either sex, if the ureter be involved, it may be possible to detect it as a thickened cord passing down from the region of the kidney.

Renal or peri-renal *new growths* may attain considerable dimensions, and thus come into close contact with neighbouring organs, so as often to lead to much difficulty in diagnosis. This is especially the case with tumours of the right kidney, which may most closely simulate tumours of the liver, both to palpation and percussion. On the left side a renal tumour may mostly be differentiated from an enlarged spleen by the points already mentioned. It may be noted that one form of neoplasm—*viz.*, renal

sarcoma—is especially common in early life; otherwise, renal cancer occurs in old subjects, like cancer elsewhere. A history of hæmaturia is not always to be obtained, for the growth in its progress may have blocked the ureter. The advancing emaciation without pyrexia, and the age of the patient, may assist in the differentiation of cancer from tubercular disease. Peri-renal tumours (generally myxomata) are rare, and the absence of any renal symptoms with them may quite obscure their diagnosis.

7. SUPRA-RENAL CAPSULE.—The position of the supra-renal capsules renders it practically impossible to determine whether an abdominal tumour in either hypochondrium has arisen from one of these organs. During life such growths present the characters of tumours of the liver or kidney; and, as they do not produce any symptoms referable to the organ in which they are seated (for cancer of the adrenals does not produce the symptoms of Addison's disease), there are no criteria upon which to rely for their diagnosis.

8. FEMALE PELVIC ORGANS.—Tumours arising in connection with the ovaries and uterus very often pass out of the narrow limits of the pelvis and occupy the abdominal cavity. Indeed, they constitute by far the majority of abdominal tumours in the female sex, and must therefore be briefly discussed in this article.

First in importance and frequency are *ovarian* (and *par-ovarian*) *cysts*, which sometimes attain enormous proportions. They may be unilocular or multilocular. If the cyst be *unilocular* and of great size, it may form a tumour that reaches from the pubes nearly to the xiphoid, and may occupy an almost central position. As a rule the tumour displaces the intestines, and dulness may be elicited over the whole area of the cyst. Fluctuation may be easily obtained, the diagnosis from ascites being founded on the fact that the flanks are resonant, and that the dulness, which may occupy the whole of the central regions, does not shift with the position of the patient. More difficulty is experienced in the diagnosis when the case is complicated with ascites, and when some coils of intestine pass in front of the tumour with which they have become adherent. In cases where the cyst has not attained so large a size, the enlargement of the abdomen is less symmetrical, and both to inspection and to measurement one or other of the two halves of the lower segment of

the abdomen will be found to be of larger size. The measurement is made by comparing on the two sides the distance between the umbilicus and anterior superior iliac spine. Then on inquiry it may be learnt that the swelling was at first more unilateral than it appears at the time of examination. In all cases of abdominal tumour in women a vaginal examination should be made; and in cases of ovarian tumour the uterus will probably be found to be drawn up or otherwise displaced by the tumour. In all cases, also, the precaution should be taken to empty the bladder and rectum before making an examination. If the cyst be *multilocular*, the diagnosis may not be so easy. The tumour is then more lobulated, firm and resisting in parts, elastic or fluctuating in others. A *dermoid cyst* would give the impression that one was dealing with a *solid growth*, whilst the latter are sometimes indistinguishable from large uterine fibroids.

The *tumours of the uterus* most likely to invade the abdominal cavity are the fibro-myomata, commonly known as fibroids—sub-peritoneal or intra-mural. Such a tumour may be felt through the abdominal wall in the hypogastric and umbilical regions as a very solid, perhaps lobulated swelling, which may not be dull on percussion in its whole extent, owing to the intervention of coils of intestine between the tumour and the parietes at the upper part of the former. Much is to be learnt by a vaginal examination conjoined with abdominal palpation in the diagnosis of such cases.

The swelling formed by a *hydrosalpinx* or *pyosalpinx* may attain such size as to be distinctly perceived in the iliac region, but the points in the differential diagnosis of such conditions will be found elsewhere. Nor need we do more than mention here the fact that an *extra-uterine pregnancy* gives rise to an abdominal tumour the true nature of which is largely inferred from the history of the case.

It is perhaps hardly necessary to mention that the *enlarged uterus* in advanced pregnancy forms a tumour capable of being mistaken for a growth; but here again the history of the case, as well as the concomitant signs of pregnancy, seldom fail to enable the observer to arrive at a right conclusion.

IV. Tumours connected with Bone.—A few words only will suffice to mention the features of new growths proceeding from the vertebral column or pelvis, and projecting into the abdominal cavity.

Sarcomata, osteomata, enchondromata, and myxomata are the more common forms of new growth in this situation; and the ilium, sacrum, or sacro-iliac synchondrosis are perhaps the chief seats of origin. Their differentiation from tumours connected with the abdominal or pelvic viscera is determined mainly by their fixity, and in the latter case by the results of vaginal and rectal exploration. Most of these tumours also are very firm and unyielding, but there are cases recorded, especially in connection with the ilium, where a rapidly growing sarcoma has not only a softer character, but is even pulsatile. Tumours growing from the ilium or sacrum sometimes extend through the sciatic notch and appear upon the buttock. In such cases sciatica may be the chief symptom.

V. Abdominal Aneurysm.—No account of abdominal tumours would be complete which failed to notice the subject of aneurysm of the abdominal aorta and its branches. These aneurysms are mostly saccular, and can be felt as more or less globular tumours generally seated in the umbilical region and to the left of the middle line. The distinctive characters of such a tumour consist in, first, its pulsatile nature, and particularly its lateral expansion, as ascertained by placing the fingers of each hand on either side of the swelling, and noting their lateral divergence with each cardiac systole; secondly, the fixity of the tumour, so that it retains its position when the patient is on his hands and knees; thirdly, the presence of a single or double bruit on auscultation over the swelling. In most cases the existence of resonance over the tumour proves that it is behind the intestines. If the aneurysmal sac be filled with clot, the tumour will feel firm, it will have no lateral pulsation, and will be indistinguishable from a tumour seated over the aorta. In cases of aneurysm there is generally a history of pain in the abdomen or back due to the pressure of the advancing tumour. The simulation of aneurysm by an abdominal abscess which pulsates by its contiguity with the vessel has been already mentioned. Another condition liable to be mistaken for aneurysm is that of so-called pulsating aorta; this is met with in the subjects of dyspepsia, hypochondriasis, and other neurotic states; it may be a source of much discomfort to them. It is differentiated by the fact that the pulsation is diffuse; there is no definite tumour, no evidence of vascular disease

elsewhere, nor history of injury, and, on auscultation, no bruit is heard unless pressure be made on the vessel. It may be necessary to examine the case under chloroform, as the patient is very likely to keep the rectus muscle rigid, and the absence of a tumour cannot be positively affirmed unless free manipulation has been practised.

VI. Phantom Tumours.—The class of "*phantom tumours*" is of some interest in abdominal diagnosis. These are swellings, generally smooth and rounded, which may occur in any part of the belly, and may come and go like a movable kidney. Met with in hysterical or neurotic subjects, a *phantom tumour* may be mistaken for a faecal tumour, or even graver conditions. Percussion sometimes yields an imperfectly resonant or even dull note, and the patient may complain that the swelling is painful and tender. Produced by localized muscular contractions or by limited distension of intestine, such a tumour may disappear during sleep and under an anæsthetic.

The following classification of the varied conditions which have been thus briefly reviewed is based upon the comparative frequency with which they produce respectively either a more or less general intumescence of the abdomen, or a swelling limited to one or other of the abdominal regions. It is not to be interpreted as indicating that the tumours mentioned are strictly confined to these regions, but only that they are most commonly found there.

A.—CONDITIONS PRODUCING GENERAL INTUMESCENCE.

Tympanites.

Ascites.

Chronic Peritonitis with Effusion.

Tubercular Peritonitis.

Cancer of Peritoneum.

To which may be added, as causing considerable enlargement extending over a great part of the abdomen—

Ovarian or Par-ovarian Cyst.

Fibroid Tumour of Uterus.

Gravid Uterus.

Distended Bladder (extreme).

B.—CONDITIONS PRODUCING PARTIAL OR LOCAL SWELLING.

SIDNEY COUPLAND.

productive power in either parent : anæmia, uræmia, jaundice, cancer, or peritonitis in the mother. Probably many of the causes to be hereafter mentioned act by causing the death of the fœtus. (2) *Diseases of the membranes or placenta.*

—Atrophy of the decidua, myxomatous degeneration of the chorion, separation of chorion or placenta with hæmorrhage into it, and hydramnios. (3) *Diseases of the uterus.*—Fibroids, cancer, endometritis, adhesions binding down the uterus and preventing its enlargement, displacements of the uterus, and possibly lacerations of the cervix.

B. *General.*—Acute febrile diseases, such as scarlatina, typhus, enteric fever, small-pox, cholera, relapsing fever, pneumonia; Bright's disease; acute atrophy of liver; diseases obstructing the circulation, such as cardiac dilatation, capillary bronchitis, cirrhosis of liver; most exhausting diseases.

C. *Accidental.*—(1) Local violence, either accidental injury or intentional interference. (2) Reflex influences, emotional disturbances, as from fright; over-fatigue or excitement; mammary irritation, as from hyper-lactation; sexual excesses; violent vomiting or purging; shock of operations, or severe general injuries. (3) Poisons: ergot, savin, rue, cantharides, carbonic acid, lead, and other rarer poisons.

D. There are patients who abort in pregnancy after pregnancy, and the cause of abortion is not discovered. It is therefore set down to a "*habit of aborting.*"

Symptoms.—Pain and hæmorrhage are the most important symptoms; if, in addition, there be dilatation of the cervix, abortion is probably imminent. Early in pregnancy, hæmorrhage usually precedes the pain, which is not severe; at a later period the pain is greater, and precedes the hæmorrhage. The pains are like those of labour, rhythmical, intermittent, referred to the pelvic region, and not affected by position; but they are far less severe. The hæmorrhage is the important symptom, and comes from uterine vessels laid open by detachment of chorion or placenta. If a small part only be detached, the vessels may become closed by thrombosis, and the pregnancy go on. If there be extensive detachment, the fœtus will die and abortion take place. As successive uterine contractions force the ovum onwards into the cervical canal, more vessels are torn through, and more blood is effused, the hæmorrhage only ceasing when the

ABORTION is the premature expulsion of the ovum before the child is viable—that is, before the end of the sixth month. Its causes may be classified as follows:—

A. *Local.*—(1) *Disease of the fœtus.*—Anything which causes the death of the fœtus may produce abortion. Among such causes are syphilis and feeble re-

uterus is empty and contracted. Sometimes, however, a dead fœtus is retained for weeks or months without provoking any attempt on the part of the uterus to expel it. In the first two months of pregnancy, the ovum is usually expelled entire; later, the membranes often rupture, and the fœtus comes away, leaving the placenta to be subsequently extruded or removed. After the first three months this is the rule.

The *diagnosis* is not difficult if the patient is known to be pregnant, although there may be difficulty in deciding as to the pregnancy. When dilatation of the cervix has taken place, abortion is inevitable. Before dilatation has occurred, the guide as to the need of interference is the amount of hæmorrhage, which should be estimated by its effect upon the patient's colour and pulse.

The chief dangers from abortion are hæmorrhage and septicæmia. The best method of arresting hæmorrhage before the cervix is dilated is to plug the cervix with a tent; after the cervix has been dilated, to empty the uterus. Septicæmia is to be prevented by antiseptic precautions.

Treatment.—(1) *Prophylactic.*—If there be reason to suspect syphilis, mercury should be given to the mother; if she be anæmic, iron may be required. Exposure to influences likely to induce abortion should be avoided, and any symptoms seeming to threaten abortion should be treated without delay.

(2) *Hæmorrhage and pain have commenced. Hæmorrhage is slight, and the cervix not dilated.* The patient should remain in bed, and take pot. bromid. gr. x, with ext. viburni prunifolii liq. ʒj (not official), every four hours. If there be pain, liq. morph. hyd. $\mathfrak{m}\mathfrak{v}$ or $\mathfrak{m}\mathfrak{x}$ may be added to this. Should the hæmorrhage continue for some days without increase in quantity, and should no further symptoms appear, the patient may be allowed to get up, and take ext. ergotæ liq. ʒss three times daily.

(3) *Hæmorrhage is profuse, and the os not dilated.*—The cervical canal should be plugged with a sponge tent, which, before it is inserted, should be dipped in a solution of corrosive sublimate in glycerine, 1 in 1000. The tent will at once restrain hæmorrhage and dilate the cervical canal.

(4) *The cervix is dilated, and hæmorrhage profuse.*—If a tent has been used, a vaginal douche of 1 in 2000 corrosive sublimate should be given. Then the anterior lip of the cervix should be

seized with a volsella and pulled down. The finger should be passed into the uterine cavity, and the ovum detached. If the finger cannot reach the fundus, it should be pressed down by the hand on the abdomen until it is within reach. When the ovum (or the placenta) has been detached, it should be grasped with a pair of ovum forceps, and extracted. Then the finger should ascertain whether the whole of the uterine contents has been removed; if small fragments are felt attached which the forceps fail to hold, the wall of the uterus may be scraped with a blunt curette. If hæmorrhage continue, the body of the uterus should be compressed between the hand on the abdomen and two fingers in the vagina; this will almost invariably stop it. Should it not, the interior of the uterus may be swabbed with a piece of cotton-wool dipped in a 1 to 6 solution of perchloride of iron. Lastly, the vagina should be syringed with a 1 in 2000 solution of corrosive sublimate. For the manipulations which have been described chloroform may be necessary, and will generally be advantageous. Under anæsthesia, the dilatation of the cervix and emptying of the uterus may be done at one operation by using Hegar's dilators. It is scarcely needful to add that hands and instruments should be scrupulously clean, and should be dipped in a 1 in 2000 solution of corrosive sublimate before putting them into the uterus.

(5) *The cervical canal is dilated, or dilating, but the hæmorrhage is not profuse.*—The patient should be advised to keep her bed, ext. ergotæ liq. ʒss being given every four hours.

(6) *The discharge contains bodies looking like white currants.*—The case is one of myxomatous degeneration of the chorion. A sponge tent should be put in the cervix, and ergot given. The uterus will then probably soon expel the tent and the diseased ovum. After the uterus has been emptied, the patient should be given ext. erg. liq. ʒss three times a day, and an antiseptic injection used twice daily. The patient should keep her bed for at least a week.

(7) *If the case be not seen until the fœtus has been expelled and the cervical canal has contracted, unless the discharges have been saved for inspection, it may be impossible to say whether or not the placenta is still in utero.* In this condition, if the hæmorrhage is slight, ergot should be given, an antiseptic douche used twice daily, and the patient

kept in bed. Under this treatment the placenta will often be expelled without ill consequences happening. If the discharge become offensive, or the hæmorrhage be profuse, the cervical canal should be dilated, and the uterine cavity explored and emptied, as described under (4). As an antiseptic douche after abortion is complete, carbolic acid 1 in 100, or Condy's fluid 3ss to Oj, may be used; but for use immediately after manipulation of the parts, sublimate is better, because more trustworthy.

G. E. HERMAN.

ACNE.—*Acne Vulgaris* is an inflammatory, usually chronic, disease of the sebaceous glands and immediately surrounding skin, resulting from the retention of plugs of altered sebum (comedones) in the gland ducts. The lesions are papular, tubercular or pustular, according to the severity of the inflammatory process, and are usually situated upon the face, neck, shoulders and back, only the palms and soles being invariably exempt from the disease. The individual lesions consist of minute, pink, acuminate papules or pimples, in the centre of which is a black-topped comedo (*A. punctata*, *A. papulosa*), or of more extensive peri-follicular infiltrations resulting—especially in strumous subjects—in chronic, livid indurations (*A. indurata*) or dermic abscesses (*A. pustulosa*); these forms usually co-exist in varying proportions, and appear in successive crops, which run a rapid course, cicatrices resulting from those which deeply implicate the cutis surrounding the gland ducts. The cicatrices are frequently the starting-point of keloid tumours. The condition, as a rule, gives rise to comparatively little pain, but exceptions are not infrequent.

Acne usually shows itself about puberty, when a remarkable development of the sebaceous gland system takes place, and is common up to the age of thirty, other forms of sebaceous disease being frequently associated with it. It affects both sexes about equally, and appears to be intimately connected with the generative organs, any functional derangements of which (menstrual disorders, sexual excesses, masturbation, &c.) are frequent concomitants, although the nature of the supposed "reflex" connection is by no means clear. It is stated that eunuchs are very rarely affected. The disease may occur in persons in robust health, but is much commoner in the debilitated and anæmic, and especially in dyspeptics who suffer from habitual constipation.

The theory that an atony of the *musculi arrectores pilorum* is the immediate cause of the retention of sebum, although highly probable and generally accepted, is obviously incapable of experimental proof. The condition is usually worse in winter than in summer; persons who have coarse, hairy, or greasy skins are specially prone to suffer from acne; there is no satisfactory evidence of its dependence upon scrofula or any other constitutional taint. The habitual use of cosmetics is probably conducive to its occurrence and continuance; it is common after variola and around patches of lupus, keloid or other diseases producing scars, probably from cicatricial obstruction to the excretory ducts.

Acne Varioliformis (*A. atrophica*, *A. frontalis*) is a rather rare form of the disease, which usually affects the forehead, temples, and hairy scalp. The eruption usually remains confined to these regions, but may occasionally spread over the neck to the back and chest. It generally occurs in middle-aged or old people, and has a marked tendency to relapse or to become chronic, with periodic exacerbations, which may occur at regular intervals. The lesions, which may be sparse or thickly aggregated, consist of small, hard, flat or acuminate papules, not preceded by comedones and not demonstrably connected with sebaceous glands; in the scalp they generally occupy the frontal, temporal and sagittal regions. They are indolent, but the majority ultimately suppurate and scab, their subsidence being followed by deep, punched-out, circular pits, which are at first pigmented, but gradually become white like the scars resulting from small-pox. By some authorities the disease is considered to be a late syphilide, but in the majority of cases evidence of syphilitic infection is certainly wanting.

Acne Cachecticorum occurs only in starved or debilitated persons after long wasting diseases, especially phthisis. Flat, livid, acneiform papules and pustules without comedones develop over the whole body, especially on the trunk and lower extremities; they cause deep, pigmented scars, and are not amenable to treatment.

Differential Diagnosis.—*Acne vulgaris* may be confounded with rosacea, pustular dermatitis-syphilis, mild varioloid, and with dermatitis due to the internal use of the bromides and iodides, or to the external application of chrysarobin, pyrogallie acid, or various tars (*see*

MEDICINAL RASHES). Acne varioliformis may be mistaken for variola, and is closely simulated by the small pustular syphilide.

Treatment of Acne.—(1) Constitutional treatment is of the first importance, and must be directed towards the anæmia, dyspepsia, constipation, or sexual derangements which usually accompany the disease; the necessity for exercise and a simple dietary must be enjoined. Among special remedies may be mentioned cod-liver oil—particularly in young persons and in *A. varioliformis*—sulphide of calcium, ergotine, phosphorus, and minute doses of perchloride of mercury, all of which are occasionally useful. The value of arsenic, except as a general tonic, is dubious.

(2) Local treatment to prove efficacious must be active and persistent; occasionally pain and inflammation indicate the use of fomentations, calamine lotion, or other soothing applications, but the majority of cases call for stimulant treatment. Comedones should be expressed at bedtime, the skin having been previously softened by steaming or bathing with hot water, then vigorous friction made with soft soap and flannel or a flesh-brush, and lotions or ointments containing sulphur (gr. xv ad 3j with glycerine and lime-water), sulphuret of potash (5j to a quart of water), corrosive sublimate (gr. j or ij ad 3j), tincture of iodine, iodized glycerine, spirits of camphor, or ichthyol applied, and allowed to remain over night. Medicated soaps containing sulphur, naphthol, or thymol are specially recommended for daily use. Indurated papules are often absorbed after the application of a belladonna or mercurial plaster, or may be touched with strong carbolic acid or the acid nitrate of mercury. Dermic abscesses ought to be freely incised, their contents expressed, and cooling lotions or compresses applied.

J. J. PRINGLE.

ACNE ROSACEA may be defined as a chronic, inflammatory, composite disease affecting the skin of the face in which erythema, hypertrophy, telangiectases, and sebaceous disorders are present in varying proportions. From this definition it will be seen that the name commonly attached to the disease is somewhat of a misnomer, the acneiform lesions being, as it were, secondary or accidental features of it. Persons, however, who have suffered from ordinary acne in early life are prone to become

the subjects of rosacea in middle life, when the disease is most common. It is generally considered to be a reflex vasomotor neurosis, and may result from disorders of digestion (especially flatulent dyspepsia with acid eructations and constipation), from habitual alcoholic excesses, and especially from menstrual disorders; this latter circumstance explains the much greater frequency, at all events of its milder, non-hypertrophic forms, in the female than in the male sex. Its subjects are frequently of neurotic temperament, and suffer from hot or cold extremities, evidences of "mobility" or ill-balance of the peripheral circulation. In such persons exposure to heat or cold, or the use of inappropriate cosmetics, may be the determining cause.

The disease is characterized by its chronicity and by the variations which it undergoes from day to day or even from hour to hour. Its mildest form is exemplified by the flushing of the nose, cheeks and ears, attended with burning or tingling sensations, which so frequently follows the ingestion of certain foods, of alcoholic stimulants, or of tea, coffee, soup, or other hot liquids. Gradually these attacks become longer in duration, until finally some erythema becomes persistent, especially about the nose and cheeks, the affected part being slightly infiltrated and of a somewhat "butterfly" shape. The colour at this stage entirely disappears upon digital pressure, and the temperature of the patch is slightly elevated; its edge is sometimes pretty clearly defined, but more usually merges gradually into the normal skin, and its extent varies with the digestive and other conditions previously referred to. The forehead and chin also frequently become implicated, and it may extend to the scalp, especially in bald persons, or more rarely still to the neck.

In a considerable proportion of cases, especially, perhaps, in persons of eczematous habit or with thick oily skins and liable to steatorrhœa, implication of the sebaceous glands is a marked and early feature. It may result in a seborrhœa oleosa, which gives the part a glistening or greasy look, or in comedones and characteristic acne lesions, culminating in "pimply" papules, tubercles and pustules, either sparsely distributed over the erythematous area or closely grouped. The consequent disfigurement is sometimes very great, and the discomfort and unhappiness derived therefrom are increased by a knowledge of a popular delusion that the condition is always the

result of intemperance. There is often general dilatation of the sebaceous gland ducts over the affected area, and it may become the seat of a secondary eczema (E. seborrhœicum), which may spread widely and mask the original nature of the malady. As the result of the long-standing over-distension of the capillaries and venules, and of the impaired tone of their coats, they dilate and become varicose, and constitute visible or even prominent objects, especially upon the ale and about the tip of the nose. Such is a picture of the commoner, non-hypertrophic type of the disease.

The hypertrophic form is much commoner in men than in women, especially in those who combine habitual alcoholic excesses with occupations which necessitate exposure to all vicissitudes of climate—e.g., bus drivers, cabmen, &c. The hypertrophy is generally confined to the nose and its immediate neighbourhood (rhinophyma, lipoma nasi). The distension of veins is usually marked, and, despite the brilliant redness, the part feels cold to the touch. The chronic inflammation, infiltration, and inflammatory new growth of the skin result in enlargement of the nose, which sometimes assumes enormous proportions; generally it is somewhat bi-lobate in form, the two halves being separated by a sulcus, and the hypertrophied organ may hang down in a pendulous manner over the upper lip and mouth. The lumen of the nostrils is not, however, usually encroached upon. From the foregoing sketch the *pathological anatomy* may be inferred. It includes congestion of the cutis vera, beginning in the lower to extend to the more superficial longitudinal plexus, paralytic distension of vessels with thickening of their coats, diapedesis of leucocytes, and the formation of new connective tissue around them, and sometimes special implication of the sebaceous glands and their ducts.

The *differential diagnosis* must be established from acne vulgaris, eczema, lupus vulgaris, lupus erythematosus, and dermatosyphilis. Only the two latter present sufficient resemblance to rosacea to render confusion probable. In L. erythematosus the presence of atrophic scarring may always be determined; but certain late syphilides closely simulate rosacea, especially when combined with iodic acneiform lesions. It appears to the writer that all three conditions (i.e., rosacea, dermatosyphilis, iodic acne) are not infrequently co-existent.

The results of *treatment* are generally

satisfactory, but seldom permanent. Careful attention to diet and regimen is of the highest importance. Alcohol is as a rule to be studiously avoided; hot tea, coffee, cocoa, and soups, spiced dishes, and starchy vegetables must be interdicted. Moderate exercise short of fatigue is generally advisable; tight-lacing is to be strongly condemned, as it appears to the writer to be a common and generally unsuspected cause of the complaint. Special attention must be paid to regular and copious action of the bowels, the drugs most generally useful for this purpose being sulphur and senna—as confection—aloes, cascara sagrada, compound liquorice powder, and the salines, preferably in the form of the purgative mineral waters of Hunyadi Janos, Carlsbad, Püllna, Friedrichshalle, &c., taken on rising, with an equal quantity of warm water. The familiar iron and magnesia mixture is often of great use. Menstrual and uterine derangements must be treated on the lines laid down in the articles devoted to them, but special reference may here be made to the utility of the prolonged warm douche in chronic inflammatory conditions of the pelvic organs.

Generally speaking, no remedy is so useful for the gastric troubles as bismuth, either in the form of carbonate or subnitrate, combined, it may be, with the alkaline bicarbonates, dilute hydrocyanic acid, and vegetable bitters according to circumstances. In other cases the dilute mineral acids are valuable, and liquor strychninae (mij to v) may be often advantageously given with them. Among supposed “vaso-motor steadying” drugs, ichthyol certainly appears to have more decidedly beneficial effects than ergot, belladonna, or arsenic; it may be given in the form of gelatine-coated pills, each containing $2\frac{1}{2}$ grains, two being taken immediately after each meal, and the dose being gradually increased according to the tolerance of the patient for the drug, which is a very disagreeable one.

Local measures are also of the highest importance. In mild erythematous phases a lactate of lead lotion is most valuable; it is made by mixing a drachm of liq. plumbi subacetatis with an ounce of fresh milk, and may be dabbed on night and morning. Calamine lotions, (gr. xx—5j ad 3j) with glycerine, lime-water, and rose-water, are of the greatest use, and, when acne is a prominent feature, sulphur lotions, as described under that head, are applicable. Hypochloride of sulphur freshly prepared (3j—3ij to the

ounce of lard) with carbonate of potash (grs. x) and a little almond oil constitutes a favourite remedy in similar circumstances, and Unna's ichthyol plasters are also useful.

Dilated veins may be opened longitudinally with a fine scalpel, free bleeding being afterwards encouraged by warm bathing, and their obliteration results from the operation, but may perhaps be more satisfactorily attained by electrolysis, the negative pole being inserted into the venule while the positive is held in the hand. A current of 2-5 milliamperes, generated by three or four cells, is usually sufficiently powerful, and does not cause scarring. Puncture of the pimply lesions with Kaposi's acne lancet and multiple linear scarifications often yield excellent cosmetic effects. Excision is the only procedure applicable to the enormous hypertrophic growths, and its results are remarkably satisfactory. the wound generally healing with great readiness.

J. J. PRINGLE.

ACONITE, Poisoning by.—The leaves and root are the parts most often taken. *Symptoms.*—A cool, numbing sensation in the mouth and throat sets in almost at once; this is followed by numbness, tingling, and loss of power in the legs. There is generally acute pain in the stomach, with vomiting and purging; the pupils are dilated, the vision impaired, and the pulse exceedingly feeble. Death may take place from syncope, and is preceded by collapse and clammy perspiration. There are no special post-mortem appearances. *Treatment.*—The patient must be kept in the recumbent position, vomiting should be encouraged by emetics, and the stomach should be washed out; digitalis (20-minim doses of the tincture) or atropine (gr. $\frac{1}{16}$ hypodermically) may be used as antidotes. Artificial respiration may be necessary; the patient must be kept warm, and stimulants freely administered.

ACROMEGALY.—The term "acromegaly" (ἄκρον, extremity; μεγάλη, large) was suggested by Marie, of Paris, for a condition which is characterized mainly by hypertrophy of the hands, feet, and face. The pathological nature of this affection is obscure. Examples of the disease have been described from time to time under various names, but the subject did not attract general attention until the publication of Marie's first paper in the *Revue de Médecine*, April 1886.

Symptoms.—The most striking feature of the disease is an enormous enlargement of the hands and feet, both bony and soft parts being involved. The hands and feet, though gigantic, are not deformed, and the skin over them is not materially altered in its appearance or in its functions. There is sometimes a disproportionate development of fat in the parts normally well supplied, such as the ulnar border of the hand and the heel. In spite of the gigantic size of the hands, they are not unwieldy, and delicate operations, such as threading a needle, are performed readily. The nails are broad, vertically grooved and occasionally large. Sometimes the wrists are enlarged, and rarely the lower part of the forearms, but the arms are never affected. The legs do not undergo general hypertrophy, but it is not uncommon to find thickening of the malleoli, head of the fibula, patella, and condyles of the femur. The face becomes elongated, and the outline oval; the nose is much broadened, the cheek-bones prominent, the lower lip thick and everted, the chin square and massive. The neck is short and thick, and partly on this account, and partly on account of the enlargement of the lower jaw, the chin tends to fall on the upper part of the sternum. The eyelids and sometimes the ears undergo hypertrophy; the tongue is often enormously enlarged. The teeth are not hypertrophied, but the intervals between them are frequently widened. In consequence of the enlargement and projection of the lower jaw, the teeth do not meet those of the upper jaw, but protrude in a very remarkable way. The frontal eminences sometimes become unduly prominent, and the vault of the skull may present some slight increase in size. The skin often has a yellowish-brown tinge, and is coarse, flabby, and somewhat dry; but these changes may be absent. In some instances, on the other hand, excessive perspiration has been noted. It is important to add that the dryness of the skin never approaches the degree of harshness seen in myxœdema. The male and female genital organs have been found hypertrophied, and sexual power may be impaired. The catamenia usually disappear early in the disease. The hair does not fall out, but is often coarse and rough; it may, however, be natural. In some instances, particularly when cachexia is present, the muscles are wasted and feeble. On the other hand, a marked

increase in muscular power has been occasionally noted. It is stated by Erb that the muscles respond more readily to electricity than in health. In the spine there is often great exaggeration of the dorsal curve with compensatory lordosis in the lumbar part. The thorax undergoes increase in the antero-posterior direction, with marked lateral flattening. The clavicles, ribs, and sternum are frequently hypertrophied. Erb has called attention to an area of dulness over the manubrium, which he believes to be due to an enlarged thymus, but this has not been constantly noted. The thyroid gland has very commonly presented some abnormality, in some cases being apparently atrophied, in others much enlarged. The laryngeal cartilages may be hypertrophied. Partly on this account, and partly in consequence of the hypertrophied tongue, the voice becomes thick and deep-toned, though quite distinct. There is frequently enlargement of the joints, not due to changes in the synovial membrane or cartilage, but to hypertrophy of the ends of the bone and to the development of exostoses. The shafts of the long bones are but little affected, and never present the characters of osteitis deformans. The pelvic bones sometimes become enlarged, and the cavity of the pelvis increased in size. A tendency to varicose veins and hæmorrhoids has been described, but no other abnormality of vessels has been detected. Marie asserts that the heart is sometimes hypertrophied. Detailed observations on the temperature are wanting. Sensations of cold, so common in myxœdema, do not occur. On the other hand, in one case there was a marked intolerance of heat. The mental faculties undergo no impairment, except perhaps in the later stages. Headache, often severe, and pains in the body, especially about the joints, are common. Erb noticed slight impairment of sensation in the hands in one case, but this would appear to be exceptional. Of the special senses, the sight is most frequently affected. Optic neuritis, passing on to atrophy, with associated blindness, has been noted in some cases. The senses of hearing, taste, and smell may be deficient. Voracious appetite, excessive thirst, and an increased quantity of urine have been observed in a few instances. One of the patients suffered from glycosuria.

The duration of the disease may be twenty years or more. The initial

symptoms in many cases are headache and suppression of the catamenia, the changes in the extremities and face occurring very gradually at a later date. In the advanced stages, cachexia supervenes, the patient becomes bedridden, and may remain in this condition for years, finally dying of exhaustion.

Diagnosis.—The disease is most likely to be confounded with myxœdema; but in acromegaly the sudoriparous and sebaceous secretions are not suppressed, the skin does not assume the dry and harsh character seen in myxœdema, the hair undergoes no marked nutritive changes and has no tendency to fall out, and bodily and mental torpor are not present. In myxœdema the bones never undergo hypertrophy, and disease of the optic nerves does not occur. From osteitis deformans acromegaly is especially distinguished by the absence of deforming changes in the shafts of the long bones, by the symmetrical distribution of the hypertrophy, and its limitation in the limbs to the hands and feet, and by the remarkable enlargement of the bones of the face, whereas in osteitis deformans the cranium is mainly or exclusively hypertrophied. Marie points out that in osteitis deformans the face is triangular with the base upwards; in acromegaly it is egg-shaped with the large end downwards, and in myxœdema it is round like the full moon. From leontiasis ossea and rheumatoid arthritis there are many and obvious points of difference, on which it is unnecessary to dwell.

Prognosis.—This has been already indicated in the description of the disease. It is sufficient here to say that there may be prolonged stationary periods, and that occasionally the disease undergoes temporary recession.

Morbid Anatomy and Pathology.—Six cases have been examined after death—viz., those of Henrot, Fritsche and Klebs, Brigidi, Marie and Broca, Fraentzel (mentioned by Virchow), and Saundby. In four of these six cases there was marked enlargement of the pituitary body, apparently a simple hypertrophy. Of the two other cases, in which this body was said to be normal, one, by Fraentzel, is believed by Marie to be a doubtful example of acromegaly; the other, by Saundby, is exceptional in the fact that the entire duration of the disease was only six months. Saundby describes atrophy of the thyroid gland with interstitial change, whereas in Henrot's case there was marked hypertro-

ply, and in Fraentzel's doubtful case this body was normal. Among other changes must be mentioned simple hypertrophy of the thymus (Fritsche and Klebs) and of the ganglia and cord of the entire sympathetic, as well as of the brachial plexus and several cranial nerves (Henrot). The changes in the skeleton were well described by Henrot, and recently have been given in great detail by Broca. According to the latter the spongy parts of the bones become hypertrophied, their porosity is exaggerated, and their nutrient foramina enlarged. Bony outgrowths are found around the articular margins, and also where there is normally any prominence, as, for example, at the points of attachment of the ligaments and tendons. The grooves in bones for the passage of vessels become extremely large. The lumbar vertebrae show the same hypertrophy of the spongy part, and in the dorsal region there is scoliosis with kyphosis. The enlargement of the face is mainly due to dilatation of the antrum. The mastoid cells and other sinuses are similarly affected. The actual cause of acromegaly must for the present be considered obscure. The scanty information derived from post-mortem examination seems to indicate that the affection depends on disease of the pituitary body. Such an assumption must be entertained reservedly, since it is possible that the hypertrophy of the pituitary, as well as of the thyroid gland and of the sympathetic, might be really local excesses of growth having no share in causation, but being simply constituent parts of the disease. Virchow discusses at great length the relation between acromegaly and various forms of local hypertrophy. He points out that it is difficult to draw a sharp line of distinction between them, but nevertheless he believes that acromegaly is an independent disorder, characterized especially by abnormal process of growth of the distal parts of the upper and lower extremities. Between this form of partial giant-growth and universal giant-growth there are many points of similarity; but there exists this important point of difference—that the former is a disease, whereas the latter is simply an unusual over-development of the normal process.

Ætiology.—The actual cause is unknown. Both sexes are affected in about equal proportion, and the disease may occur at any period between the ages of fifteen and sixty. Heredity is believed by Virchow to have an important share in

causation. In several cases there was an early cessation of the catamenia, but this was probably a symptom of the disease. Acromegaly occasionally occurs about the period of puberty, and this fact, together with the early arrest of the catamenia, has led some observers to the gratuitous assumption that the disease has some relation with the sexual processes or changes in the sexual development.

Treatment.—Treatment is to be conducted on general principles. Massage is favourably mentioned by one observer.

ACTINOMYCOSIS is the name given by Bollinger,¹ at the suggestion of the botanist Harz, to a disease which is of frequent occurrence in cattle. A similar, if not identical, disease has been recognized in man.²

The name is derived from the presence of a characteristic micro-parasite, *the ray fungus*, which is found in the affected tissues.

FIG. 1.

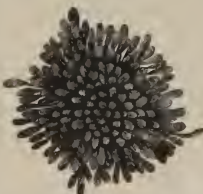

FIG. 2.

Actinomyces, showing—

Fig. 1. Clubs, as usually found in cattle.

Fig. 2. Method of spreading (low power).

FIG. 3.

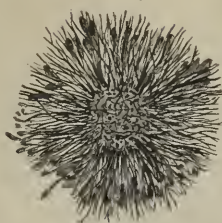

FIG. 3. Threads, as usually found in man (highly magnified).

Its manifestations are essentially those of chronic inflammation, with or without suppuration, often resulting in the formation of granulation tumours.

The disease cannot with certainty be recognized except by the detection of the fungus in the discharges, or in the substance of the infected part, although in many cases the peculiar structure of the tumours has given the clue to a correct diagnosis.³ The symptoms depend more on the locality of the tumours than on the nature of the organism.

This disease has not unreasonably been mistaken for many other affections, such as tubercle, osteo-sarcoma, strumous abscess, &c., the organism having in most cases been overlooked. Not however in all, for Langenbeck operated on a case in 1845, and Lebert⁴ in 1857 and Robin⁵ in 1871 gave figures of the organism, without recognizing the true nature of the disease.

It was not until 1876 that Bollinger¹ threw new light upon the subject by showing that many of the tumours which are common in cattle are in reality caused by the presence of a definite organism. In 1877 Israel² published observations on a similar disorder in man. It was not, however, until 1879 that Ponfick⁶ insisted on the identity of the organism found in man with that found in cattle. This statement was accepted without definite proof, and much confusion has been caused by descriptions of the organisms found in man being taken from specimens of actinomycosis bovis.

The history of the affection is nowhere better given, in English, than in Professor Crookshank's valuable Appendix to the Report of the Agricultural Department of the Privy Council for 1888, to which the writer is indebted for much information and for many references.⁷

The first case in this country was recognized by the writer, in conjunction with Dr. Sharkey, when investigating

the microscopic appearances of an abscess of the liver. Considerable light has been thrown on the structure of the growth by these researches, and the observations have been amply confirmed in this country and in Germany. They tend to show that in most cases the organism in man differs from that found in actinomycosis bovis, and help to confirm the accuracy of Israel's original drawings. It is probable that the organism is polymorphic, and that, although the forms are different, the fungus is the same under different conditions of growth. Dr. Crookshank's inoculation experiments are in support of this view: and intermediate stages have been found by Delépine, Eve, and Macfadyan,⁸ whose observations fill up the gaps hitherto existing in the chain of evidence which connects the various forms found in cattle with those found in man.

The fungus grows embedded in the tissues or floating in the pus. In the latter are seen minute spherical granules, varying in size from a small pin's head downwards. The granules appear sulphur-yellow by reflected, and greenish-yellow by transmitted light, and in the discharge from a tumour which is suppurating freely are often very numerous.

These granules consist of masses of the fungus from which the disease has received its name, together with degenerated inflammatory products.

When looked at under the microscope with a low power, and by reflected light, they closely resemble a minute raspberry. They have a rough, granular surface, which superficially seems to be composed entirely of club-shaped bodies radiating from a common centre. With a higher power, and after the action of reagents such as benzole and caustic potash, much of the intervening fatty debris is dissolved away, and it is seen that the spherule consists of a central core of fine mycelial threads, with a varying number of club-shaped bodies radiating from it. Some of the clubs consist of segmented rods with bulbous extremities, some are digitate, some palmate. The connection between the clubs and the threads has been minutely investigated by Crookshank and Taylor, who find that the clubs consist of an external sheath continuous with, and an expansion of, the protoplasm of the thread, which runs up into and constitutes at its termination the central core of the club. These observations have been confirmed by Delépine. Amongst

the threads there are often found minute spherical bodies which are supposed to be spores. The number of clubs varies greatly in different specimens: in some the growths seem to consist almost entirely of threads,⁹ in others of clubs,¹⁰ though in all cases clubs and threads have been ultimately detected; but the reactions seem not to be identical with those given by actinomycosis bovis.

There is much doubt as to the true nature of the growth; it has been generally accepted in Germany that it is a bacterium,¹¹ and that the club-shaped bodies are only degenerative forms.⁸ This is contrary to analogy, and is, it would seem, founded on the result of imperfect cultivation experiments.¹² There can be little doubt that it is a mould, that the threads are delicate hyphæ forming a dense mycelium, and that the clubs are organs of fructification analogous to the asci of ascomycetes (Delépine).

The best mode of staining the threads is by Gram's method:—Saturated alcoholic solution of gentian violet 10 per cent. in aniline water decolorized in solution of iodine 1 part, iodide of potassium 2 parts, water 300 parts, and then in alcohol. To stain the clubs as found in man is difficult; the best results have been obtained with orange rubine or eosin.

Morbid Anatomy.—The appearances presented by the tumours vary according to the structure of the tissues primarily attacked. It is remarkable that in most of the cases recorded in England the liver has been affected, and has seemed to be the primary point of infection. In this organ the structure of the growth is very characteristic (an excellent engraving is given by Mr. Shattock in the St. Thomas's Hospital Reports, vol. xv., 1885, p. 235). It consists of minute foci of inflammation, which tend to run together, forming larger areas. These again unite, forming small abscess cavities filled with thick creamy pus, separated from each other by dense bands of fibrous tissue. By this process, as it extends, the disease slowly destroys the proper tissue of the affected part, and replaces it by a sponge-like mass of interlacing fibrous bands filled with pus, the amount of pus being greater in proportion as the course of the disease is rapid.

In the extremely chronic example of the disease seen in the tongues of cattle (wooden tongue) the growth consists almost entirely of fibrous tissue,

embedded in which are minute specks of inflammation, the organism being the central spot of each inflammatory area.

In the softer and more rapidly extending growths, such as occur in the thorax, masses of the fungus are found floating in a pultaceous mass of pus, mixed with products of inflammatory degeneration.

If very chronic, the tumours may become calcified, or even partly converted into bone.

The disease spreads by the formation of secondary foci of inflammation caused by the transportation of the fungus.

Nothing certain is known of the communicability of the disease from cattle to man, and the origin of the disease itself is doubtful.

Treatment.—No drug is known to exert any specific influence on the organism. Removal of the infected tissue is the only method which holds out any chance of ultimate success. If the main growth can be removed, there is hope of complete recovery.

ADDISON'S DISEASE is characterized clinically by a progressive asthenia with a great liability to nausea and vomiting, and usually, if not always, by a peculiar discoloration of the skin.

Symptoms.—The onset of the disease is almost invariably gradual. Sometimes the discoloration is the first thing noticed, but in the majority of cases, at

any rate, an increasing debility will have already set in. The patient, though often anæmic, is not necessarily so to any marked degree, and, though there may be wasting, there is not, as a rule, great emaciation. The extreme weakness, for which no sufficient signs of organic disease can be found, is the chief feature of the early stages. The heart-sounds are clear but weak, the pulse small and frequent, and the patient suffers from breathlessness, cold extremities, and a tendency to faintness. He has a downcast, sad look, and constantly complains of weariness; the nervous enfeeblement affects the mind as well as the body. Anorexia, nausea, and vomiting are generally present; they usually appear early in the disease, and recur at intervals. The bowels are sometimes confined, sometimes relaxed, and that without any obvious cause; the urine is pale and free from albumen, and may be increased in quantity. As a rule, the temperature is below the normal. Amongst other symptoms, more or less pain in the loins and epigastrium, vertigo, tinnitus, and headache are often present. The discoloration or bronzing of the skin, as it has rather erroneously been called, is probably not an essential feature, but it is found in a large majority of the cases. It is due to an increase in the normal amount of pigmentation, and even when most extensive, and affecting the whole body, is never uniform throughout, except in places where the skin has suffered injury or abrasion, as from recent blistering; but no sharp lines of demarcation will be found. The change occurs in small patches or diffused areas, varying in colour from a light yellow or greenish brown to a slaty blue-black shade or deep olive tint. It is usually first seen on the face; and here, and on the neck, and backs of the hands—*i.e.*, in the exposed regions of the body—it is most marked. It is merely an exaggeration of the normal pigment of the part, and is therefore very marked on the penis and scrotum and about the nipples. It is also seen on the parts subjected to friction—*e.g.*, the site of the garters. Scars that are not very deep and places where blisters have been applied are apt to become highly pigmented. The sclerotics are always pearly white, in strong contrast to the rest of the patient's face; the nails, hair, and teeth may show increased pigmentation, and in one case an increase of pigment was found in the pia mater. Fagge surmises that if persons were kept in the dark or not exposed

to sunlight, even if suffering from this disease, they would remain pale. Here and there on the body a few small spots like pigmented moles will be seen. The mucous membranes may also be affected, and patches may be found on the lips, palate, cheeks, sides and under-surface of the tongue, and in the vagina. The intensity of the colour may vary with the patient's general health, and leucoderma may co-exist. The disease progresses, but not always at a uniform rate, to a fatal termination. The prostration increases so that the patient is confined to bed or to the recumbent position, from which he cannot move without great risk of syncope; his voice becomes weak, and he is constantly sighing or yawning or troubled with hiccough. The intellect gradually becomes dulled, and delirium, coma, and convulsions usher in the termination, or the patient is carried off by incoercible vomiting and diarrhoea. In a considerable number of cases death occurs suddenly from syncope during some slight exertion. It is believed that the disease is invariably fatal, and there is evidence that the cases in which no discoloration is observed run the shortest course. There may be periods of remission, and the illness may be prolonged for a few years, but it usually terminates in about eighteen months.

The *diagnosis* is always difficult, especially in the early stages, when discoloration is slight or absent, and it is probable that some of the fatal cases of so-called nostalgia which have been recorded were, in reality, instances of this disease. Where the asthenia and pigmentation are both well marked, there need not be much hesitation in pronouncing an opinion, but it must be remembered that pigmentation is met with in abdominal cancer and tuberculosis, lymphoma, pregnancy, chronic uterine disease, hepatic disorders, and melanotic cancer.

Pathology.—An increase of pigment is found in the cells of the rete mucosum, chiefly in the lower layers; also in the deeper parts of the connective tissue, the cells of the papillæ, and in the subcutaneous tissues. It is said that this pigment contains no iron, thus differing from the normal pigment. It is elaborated in the deeper cells about the vessels of the corium, from whence it passes to the more superficial layers. Chronic phthisis or general tuberculosis will often be found; the heart is sometimes small, and the spleen occasionally enlarged; but the chief interest centres round the suprarenal bodies and adjacent structures.

The commonest change, and one that for a long time was believed to be essential, is a caseo-fibrous one, whereby the capsules are enlarged, though retaining their normal shape, and are adherent to the structures in their immediate neighbourhood. In this state they are firm or indurated, and on section show greyish-white or caseous nodules of various sizes, the rest of the organ presenting a semi-translucent, greyish aspect; or the whole may have undergone caseation; the caseous areas may be softened into a creamy material or may have become calcareous. When this latter process has not occurred, the final stage is one of absorption, the capsule shrinking into a small, puckered, fibrous mass, adherent to the structures round it, being then much smaller than normal and recognized only with difficulty. Fagge describes the earliest change as the formation in the medullary part of a firm grey or whitish mass more or less nodulated at the growing edge, with clusters of bodies like miliary tubercles round it. This spreads into and destroys the cortical part, an enlarged, hard, uniformly greyish mass resulting. The next stage is that of caseation. Microscopically, at the commencement small, round, lymphoid cells are seen in the meshes of a delicate, wavy, fibrillated stroma; the subsequent appearances are those always present in tuberculosis. Tubercle bacilli have been demonstrated to be present. Some undoubted cases of this disease, however, have been recorded in which the supra-renal bodies had not undergone this change, but were found atrophied either from interstitial changes or apparently from mere wasting. Other diseases of the capsules, such as cancer, are probably never followed by the special symptoms of this disease. Amongst the structures to which the capsules are sometimes adherent are the semilunar ganglia and the plexus of nerves in connection therewith, and sclerotic changes have sometimes been found in these, the nerve cells being deeply pigmented, whilst both fibres and nerve cells may be compressed and ultimately destroyed by the growth of connective tissue taking place between them. The examination of these parts is often a matter of some difficulty, and requires to be conducted with the greatest care. After removal of the intestines it is usually considered the best plan to remove the liver, kidneys, supra-renal capsules, ganglia, &c., *en masse*, and afterwards to dissect them from behind; if

great care be not taken, the very existence of the capsules may be overlooked, owing to the extreme wasting.

Etiology.—The causes of the disease are unknown. It is much more common in males than in females, and is most often met with between the ages of twenty and forty; it is very rare in children under ten, or in persons over fifty. It is more common amongst the working classes than amongst the well-to-do, possibly because the former are much more exposed to injury, as it has sometimes seemed to follow upon an injury to the abdomen or back, and in not a few cases it has been associated with caries of the spine. It is not, strictly speaking, an hereditary affection, nor, though it is frequently dependent upon tubercular disease, is it more common amongst phthisical families. No theory as to the nature of Addison's disease which satisfactorily meets all the difficulties has yet been framed, and during late years pathological opinion has wavered between the view that the changes in the capsules are primary and all important, and that which regards these as secondary to an inflammatory condition of the neighbouring sympathetic nerves and ganglia; but at the present time the balance of authority is strongly in favour of the theory that the disease is primary in the adrenals, and that the changes found therein are due to the presence of tubercle.

Treatment.—There is no specific against this malady, nor is any drug known to have ever exercised any influence over its course, although there is often a remission of urgent symptoms for considerable periods; the treatment, therefore, can only be symptomatic. The patient should be warned of the liability to syncope, and in the late stages should be strictly confined to the recumbent position. The diet should be most carefully regulated (remembering that vomiting and diarrhoea are very apt to occur and difficult to check), and the strength maintained by such general tonics as may seem indicated.

JOHN ABERCROMBIE.

ADENOID VEGETATIONS, a term applied to hypertrophy of the adenoid tissue, normally existing in the nasopharynx, to which the name of Luschka's tonsil has been given.

Symptoms.—In a characteristic case the symptoms are so marked that they are at once recognized by the practised observer. The points which most attract attention

are the vacant expression of the child, the open mouth, and usually somewhat noisy breathing. The face is elongated, and the nose narrow. It will probably be found that the patient's hearing is more or less impaired, and that at times he suffers from an increased amount of deafness, accompanied by earache and discharge from the ears. The child usually suffers also from a hacking cough, is very subject to attacks of cold in the head and laryngeal and bronchial catarrh, snores at night, and mucus tinged with blood will often be found staining the pillow in the morning. Over and above the appearance of stupidity, produced by the mouth being kept habitually half-open, and the deafness, there is no doubt that the existence of these growths does influence unfavourably the mental condition and lead to a want of the power of application. When the child talks the voice has a muffled character, the so-called "deadness of speech," with inability to pronounce the nasal consonants *m* and *n*. Enlarged tonsils and granulations at the back of the pharynx are often found associated with adenoid vegetations. Owing to the constant secretion kept up by the presence of these growths, a muco-purulent discharge will be seen trickling down the pharynx. If a rhinoscopic examination is practicable, the naso-pharynx will be found more or less occupied by these growths, so that the normal outlines of the septum and choanæ are obscured. If the examination by means of the mirror fails to give satisfactory information, a digital investigation may be made, and, on introducing the finger behind the soft palate, the vegetations may be recognized by the touch: if small, they have a velvety feel; if larger, they impart the sensation of a bag of worms. On account of their vascularity, there is usually blood on the finger when it is withdrawn. Adenoid vegetations are often associated with a lateral narrowing of the alveolar arch and prominence of the upper incisor teeth, and their presence exercises an unfavourable influence on the development of the chest, which becomes pigeon-breasted. Hernia has recently been attributed to nasal stenosis, the frequent and long-continued efforts on the part of the patient to get rid of the secretion from the nasal passages giving rise to increased abdominal pressure. That adenoid vegetations exert an injurious influence on the physical development of children is shown by the rapid increase in height and weight which follows

their removal by operation. The writer is in the habit of noting down the height and weight of patients before and after operation, and he has been much struck by the alteration experienced, especially in the case of children who had previously been stunted in growth.

Pathology.—Adenoid vegetations precisely resemble in their structure enlarged tonsils and the granulations seen in the posterior wall of the pharynx.

Ætiology.—Youth is the most important predisposing cause, as with advancing years the growths have a natural tendency to shrivel up and disappear, but, too often, not before they have done grave and permanent damage. They are met with in all classes of life and in all climates, but they occur especially in temperate and moist climates. Some authors regard them as an outcome of the scrofulous diathesis, but this view requires further corroboration.

Treatment.—Too much stress cannot be laid on the importance of the early and complete removal of these growths, and on the folly of waiting for their spontaneous disappearance. Between the ages of four and twelve is the best time for the operation, but the writer has seen good results in patients of fifteen and sixteen. Older patients derive much less benefit from operation, as in them permanent changes have probably already taken place as the result of the presence of these vegetations. Various methods of removal have been suggested, but the writer is of opinion that the most satisfactory method is to place the patient under chloroform, and to thoroughly clear out the naso-pharynx at one sitting by means of Loewenberg's forceps. This procedure has the advantage of allowing the tonsils to be excised at the time if, as is so frequently the case, they are enlarged, and, if need be, portions of the inferior turbinated bodies may also be removed. For full details of the operation the reader is referred to an able article by Butlin in vol. xxi. of St. Bartholomew's Hospital Reports.

F. DE HAVILLAND HALL.

AGORAPHOBIA, a fear of open places.—This symptom, first described by Beard, occurs, usually in association with others of greater importance, in cases of neurasthenia and in persons of neurotic inheritance. The fear seizes the patient indifferently in a large crowded square of a town or upon a lonely plain. The dread which many people have of looking down from a height is a strictly

parallel psychical state. Agoraphobia is comparable to some sensations of the insane, such as that of the body growing too large for the room, shrivelling, or becoming buoyant.

AIR, COMPRESSED, Therapeutics of.—Several forms of apparatus have been devised for the purpose of inhaling compressed air, the most practical being constructed upon the principle of the gasometer (Waldenburg's), or upon that of the accordion. In either of these the pressure can be regulated with some degree of precision, and is under the control of the patient. A more complete method of inhaling compressed air is by means of the compressed-air bath. These baths are to be found at several places on the Continent, and have been much used. In this country there is one at the Brompton Hospital for Consumption (where, also, a pneumatic cabinet, mounted on strong wheels and arranged for use, either with compressed or rarefied air, has recently been introduced), and a few others at Ben Rhydding and other health resorts, but their use has not as yet become general. They consist essentially of small iron chambers, capable of holding from one to four persons, and rendered completely air-tight. Air is forced in at the lower part of the chamber and allowed to escape through a graduated outlet at the roof, the degree of pressure being carefully regulated by this means. A compressed-air bath should last about two hours, the pressure, which may range between 2 and 10 lb., being increased very gradually at first, until it reaches the maximum that is required, and, when this degree of pressure has been retained for about one hour, it should be as gradually diminished, till the normal atmospheric pressure is again reached. The effect of compressed air upon the lungs, by whichever method it be inhaled, is to cause greater depth of inspiration, and consequently greater expansion of the lung tissue. The number of respirations per minute becomes slower. The heart's action also is slowed by several beats, and the arterial tension is very considerably increased. The chief physiological action is the introduction of a larger proportion of oxygen with each inspiration, and hence the induction of more rapid tissue changes. The cases most suitable for treatment by this method are chronic inflammatory conditions which have been followed by collapse of lung tissue or temporary

closure of bronchioles. By some observers the compressed air is said to have a direct sedative action upon the respiratory passages, and so to be of value in cases of asthmatic dyspnoea. In all conditions, its effects are in the first instance temporary only, and the forced expansion of the lung is not maintained. After prolonged use of the bath, however, a more or less permanent expansion is gradually induced, which is accompanied by marked relief to the dyspnoea, but to obtain such a result, upwards of a hundred baths are sometimes necessary. The temporary relief in some cases of chronic bronchitis and emphysema, or of the latter condition without any inflammatory change, is very decided. In cases of chronic pleurisy, where the lung has become bound down and partly disused and collapsed, the force of compressed air may be advantageously employed to re-open as much of the shrunken tissue as may be capable of re-expansion, and in certain cases of imperfect recovery after acute pneumonia it may have a beneficial effect. In cases of phthisis compressed air must be used with caution. It would appear to be most efficacious in those cases where the disease is not active, and where there is but little evidence of any inflammatory condition of the mucous membrane. It should not be used where there is any tendency to hæmorrhage, or where the disease appears to be progressing rapidly. The treatment is contra-indicated in all cases of marked arterial degeneration from whatever cause, and in all cases where there is any reason to anticipate hæmorrhage from any of the internal organs, as the stomach, uterus, kidney, &c. Compressed air is not suitable for old persons, nor for those in whom the chest-walls have become rigid.

E. C. BEALE.

AIR, RAREFIED, Therapeutics of.—Rarefied air may be employed as a remedial agent either by means of apparatus similar in construction to that used for the inhalation of compressed air, or by a residence at high altitudes in some of the mountain health resorts. Its immediate effect upon the function of respiration is to increase the muscular efforts required to fill the chest, and by this increased effort a certain amount of lung tissue becomes re-expanded which in ordinary shallow breathing has been allowed to remain at rest, and perhaps collapsed; the expiratory movements at the same time are more

complete, and the average of residual air and carbonic acid left in the lungs after each respiration is less than before. By this means, therefore, an increased degree of tissue change is induced, and, when the treatment is persevered with for a long period, the lungs themselves tend to become more or less permanently increased in capacity. Various methods have been tried whereby the inhalation of compressed air might be so combined with expiration into rarefied air as to increase still further this mechanical expansion of the lungs, but hitherto the results obtained have not been satisfactory enough to warrant the adoption of the method as a regular method of treatment. Expiration into rarefied air has, however, been found to be beneficial to certain cases of emphysema by assisting the more complete emptying of the chest of the regular tidal air and of some of the residual carbonic acid, which is rendered difficult in that disease by the loss of elasticity of the vesicular tissue.

E. C. BEALE.

ALBINISMUS is the congenital absence of pigment from the skin, hair, choroids and irides. The condition is frequently hereditary and generally affects more than one member of the same family. The hair is usually white, fine, and silky, but occasionally its colour is reddish. Photophobia and nystagmus are usually present; the iris appears pink, and the pupil has a dark-red spot in its centre. Albinos are frequently poorly developed, both mentally and physically, but the rule is by no means an invariable one. Partial albinismus is fairly common among negroes, giving them a "piebald" appearance. The patches occasionally occupy the area of distribution of some nerve; the eyes are usually unaffected. Some cases are said to recover.

ALBUMINOID DISEASE is also known as waxy, amyloid, or lardaceous infiltration or degeneration. It is a peculiar change, usually affecting several of the viscera at the same time, and supervening upon, and in consequence of, some pre-existing disease. The spleen, liver, kidneys, intestine, and lymphatic glands are the organs most frequently affected, and in the order named. The first result is to produce an increase in size of the organ, which is pale, and, on section, presents a glistening, waxy, bacon-like appearance. The change always commences in, or in connection

with, the capillary vessels. In the spleen it is first seen, and is most marked in the Malpighian bodies, which become visible to the unaided eye, looking like grains of boiled sago, whence comes the term "sago-spleen." In the liver the change commences in the hepatic capillaries, and consequently first affects the intermediate zone in each lobule. The liver cells are not infiltrated. In the kidney it is often confined to the glomeruli, or some of the afferent arteries may also be affected. Occasionally the cortex escapes, and the straight vessels in the pyramids are invaded. Not infrequently albuminoid disease of the kidney is accompanied by some other form of chronic renal mischief. In the small intestine the blood-vessels of the villi show infiltration. The change is found less often in the stomach, and still less frequently in the large intestine. Albuminoid deposit has also been found in the pancreas, supra-renals, in the skin, in certain new formations, and in the endothelial lining of the aorta. In a few instances renal casts have given reactions characteristic of this change. In the later stages the organs may be found so enormously enlarged that the liver, for example, almost fills the abdominal cavity, and the spleen may reach a hand's breadth below the costal margin. If the cause of the disease be removed, the infiltration may be absorbed, the affected organs returning to the normal size. The *iodine test* for the lardaceous change is easy of application, and reliable. The cut surface of the organ having been rendered free from blood by washing, a solution of iodine, alone or with iodide of potassium, is poured over it, when the affected parts will become of a deep mahogany-brown colour, the degree of staining depending upon the amount of disease. This test can be applied to a section under the microscope in a doubtful case, or the following microscopical test may be used:—The section is stained with methyl-aniline violet, and mounted in glycerine, acidulated with acetic acid; the affected parts take the stain very readily, and the addition of acetic acid turns the parts so stained a bluish-violet colour. Whether the albuminoid change be of the nature of an infiltration from the blood or a primary degeneration is a point on which there has been much dispute, and which even now is not finally settled. On the one hand, it is contended that in this disease there has been a deposition of the fibrin or albumen of the blood modified by the loss of alkali or the addition

of an acid—that lardacein is, in fact, nothing more than de-alkalized fibrin (Dickinson); whilst, on the other hand, it is pointed out that de-alkalized fibrin is really syntonin, and that nothing like lardacein has ever been discovered in the blood, and cannot, therefore, have been deposited from it.

Ætiology.—The conditions under which the change occurs are in cases of chronic suppuration secondary to bone or joint disease; also of phthisis, empyema, pyelitis, ulceration of the skin; of syphilis with or without bone disease or suppuration; it is said that congenital syphilis alone may be a cause. Other causes have been named, such as malaria, malignant growths, &c., but more evidence is required on this head. Very little is known as to the length of time required for the production of the disease; much depends upon the severity of the original affection.

As a rule, the change appears in several of the viscera about the same time, and a *diagnosis* would be justified by the simultaneous occurrence of a smooth enlargement of the liver and spleen, unaccompanied by jaundice or ascites, together with albuminuria, diarrhoea, and a waxy cachectic complexion. As has been already stated, other forms of Bright's disease may co-exist, so that the signs of a chronic nephritis should not exclude the diagnosis of albuminoid disease.

Treatment.—In the syphilitic cases it would be always worth while to give iodide of potassium and mercury a trial, and examples of apparently complete recovery have been recorded. In the other cases, good food, pure air, iron, cod-liver oil, and quinine are the most important remedial measures, and perhaps the salts of potassium might be beneficial. The removal of the cause, if it be possible, is the only reliable means of arresting the disease.

ALBUMINURIA.—Various forms of albuminous matter are at times found in pathological urines, but that which clinically is known as albumin is a mixture of serum albumin and serum globulin in various proportions. In behaviour to the ordinary tests these are identical, and for practical purposes are detected and estimated as one body.

TESTS FOR ALBUMEN.—*Heat.*—Generally speaking an acid albuminous urine, when boiled, becomes turbid, from the coagulation of the albumen, and the turbidity does not disappear when a few drops of acid are added. This when

properly carried out, constitutes one of the most delicate tests for albumen. The urine should be clear, or, if not so, should be filtered. A turbidity from the presence of urates does not interfere much with the reaction, since such turbidity will disappear at a temperature below that required to coagulate the albumen. The proper acidity of the urine is of the greatest importance. In an alkaline urine the albumen tends to become alkali-albumen, which is not coagulated by heat. Moreover, in such urine the phosphates are deposited on heating, although afterwards dissolved by the addition of acid (*see PHOSPHATES IN THE URINE*). Similarly in a too-acid urine, a small quantity of albumen may be changed into acid albumen, and again become non-coagulable by heat. A most common error arises from this fallacy, in that a test-tube, imperfectly cleaned, may contain a sufficient amount of nitric acid to acidify its contents and prevent coagulation. The test should be carried out thus:—A tube, some 6 inches in length, should be filled to about two-thirds of its length with the urine to be examined. The reaction of the urine being ascertained, it should be rendered neutral by the addition of either dilute acetic acid or of liquor potassæ, as may be required. Dilute acetic acid is now to be added until the reaction is faintly acid, and then still one drop more of the acid. The test-tube being held by its *lower* part, the *upper* part of the column of urine is boiled over a flame; the albumen, if contained therein, is shown as a white cloud, which is the more easily seen when the upper part of the column of urine is contrasted with the lower and unboiled portion. As additional security, a few drops more of acetic acid may be now poured in to dissolve any phosphates which might possibly have been precipitated. As is seen, there are very many fallacies in connection with this test, and the following is generally preferable.

Nitric Acid.—Nitric acid coagulates albumen. The best method of applying this reaction clinically is to pour a little fuming nitric acid into a test-tube, and then, inclining the tube as much as possible, allow the urine to flow gently down the side, so as to float on the surface of the denser acid to the height of about an inch. At the line of junction of the two fluids, the albumen, if present, is coagulated, forming a white ring, which, if only a small quantity be pre-

sent, may not appear for some fifteen or more minutes. Frequently, immediately above the albumen ring, is seen a more hazy zone, believed to consist of mucin, though this is doubted by the writer. This ring disappears if the tube be slightly shaken. Urine containing large quantities of urates will precipitate them on the addition of the acid; but the cloud thereby produced is usually first seen at the top of the urine column, and disappears when the urine is warmed. Similarly, copaiba and cubebs, if taken internally, appear in the urine and are precipitated by the acid; but these again disappear on the application of slight heat. A coloured ring is very frequently seen at the junction of the acid and the urine, and may hinder the recognition of the albumen cloud. Such a ring appears in urines which contain an excessive amount of indican or skatol absorbed from the intestine, and in the urine of persons who are jaundiced, or who have taken iodides or bromides internally.

In the opinion of the writer the best test for albumen in the urine is the *magnesium-nitric test*, recommended by Sir William Roberts, and not to be confused with the acidulated-brine test of the same observer. The magnesium-nitric test is made by mixing one part of strong nitric acid with five parts of a saturated solution of sulphate of magnesium. It is applied in exactly the same way as the nitric-acid test. Its advantages over the ordinary nitric-acid test are that it is more delicate, the albumen ring being denser and appearing more rapidly, whilst the fluid used is not so corrosive.

Picric Acid.—A saturated solution of picric acid constitutes, when used with care, a very delicate test for albumen. It may be applied by the contact method, as described above, though it is much more difficult to keep the two fluids separate than in the case of the nitric-acid tests. Picric acid also throws down peptones, albumose, mucin, and quinine, but the clouds produced by the precipitation of these bodies are removed by heat.

A large number of other coagulation tests for albumen have been put forward in recent years, among which may be specially mentioned acidulated brine, ferrocyanide of potassium, tungstate of soda, and potassio-mercuric iodide. All of these are extremely sensitive, but are prone to give indications of the presence of albumen in what are normal urines. A convenient method of applying some

of them is by means of Dr. Oliver's test papers (see his "Bedside Urine Testing").

To separate serum globulin from serum albumin the urine should be neutralized, and a large quantity of solid magnesium sulphate added to it. The mixture is then to be allowed to stand for some hours—best at a temperature of about 35° C. The globulin is thus precipitated, and its separation is hastened and rendered more complete if the mixture be repeatedly shaken. It is to be noted that the globulin is precipitated, not coagulated, and it can therefore be filtered off and re-dissolved in water, the albumin remaining in the original solution.

QUANTITATIVE ESTIMATION OF ALBUMEN.—The most accurate method of ascertaining the quantity of albumen present in a given fluid is by precipitation and weighing, but this method is so troublesome, and requires so much special technique, as to be useless for clinical purposes.

As a rough method of estimation, a column of the urine may be acidified in a test-tube and thoroughly boiled. The tube is then allowed to stand for a little time until the coagulated albumen has collected at the bottom of the tube. The height of the column of albumen is then compared with the height of the whole column of urine, and expressed as a fractional proportion, such as a half, a quarter, a twelfth, and so forth. The writer finds it not unnecessary to insert a warning that such proportion refers only to the relative heights of the columns of albumen and urine respectively, and not to the actual amount of albumen present in the whole urine.

A similar but much more accurate method is that of Esbach. The urine to be examined is first diluted to a specific gravity of not more than 1010, and, if necessary, should be rendered acid with acetic acid. It is then poured into a special graduated tube up to a line *u*, and to it is added a mixture of equal parts of saturated solutions of picric and citric acids up to a line *r*. The solutions are well mixed, and allowed to stand for twenty-four hours, at the end of which time the coagulated albumen has subsided to the lower portion of the tube, and its height is read off on a graduated scale, which gives the proportion of grammes per litre.

The dilution method was proposed by Sir William Roberts. By this method the albuminous urine is diluted with

water until, when nitric acid is added, it will give an opacity before forty-five seconds have elapsed, but not before thirty seconds. The observer, with a watch before him, adds nitric acid to the urine by means of a pipette, so that the acid sinks to the bottom of the tube. Should the opacity appear before thirty seconds, the urine is diluted with so many times its own bulk of water as will suffice to produce the desired reaction. The quantity of water added is expressed in terms of the original bulk of the urine employed, as degrees of dilution. It is found by actual weighing that each degree of dilution corresponds to 0.0034 per cent., or to 0.0148 grain per fluid ounce. For further details Sir William Roberts's account in his work on "Urinary Diseases" may be referred to.

For Dr. Oliver's method by the use of test-papers, his work on urine testing should be consulted.

ETIOLOGY OF ALBUMINURIA.—Albumen may accidentally reach the urine from the admixture with it of some albuminous fluid, such as pus or blood. This is not true albuminuria, and is readily distinguished from it by the detection of the other elements of the admixed fluid. It must be borne in mind, however, that cases occur in which, although pus be present in the urine, true albuminuria may co-exist, and it is often a matter of importance to determine whether the amount of albumen present is more than would be accounted for by the pus discovered.

The causes of albuminuria may for practical purposes be grouped as follows:—

1. *Organic Disease of the Kidneys.*—From this cause albuminuria is found in acute and chronic Bright's disease, abscess and tumours of the kidney, and inflammation of the kidney spreading to it from the pelvis of the organ. In most cases of diabetic coma albumen is found in the urine, and is probably caused by the changes in the renal epithelium known to exist in this state.

2. *Pyrexia.*—Febrile disorders of all kinds are prone to be accompanied by the presence of a small amount of albumen in the urine, which disappears when the febrile action ceases. This incidental albuminuria is entirely independent of the cause of the pyrexia. It may occur when the fever is due to some local inflammation, just as when it is part of a general zymotic disorder. Nevertheless, during the pyrexia of pneumonia and diphtheria, albuminuria is specially

marked. It is to be distinguished from the more serious albuminuria which is a characteristic of certain specific fevers, such as scarlet fever, and which is due to the supervention of Bright's disease upon the original disorder.

3. *Congestion of the Kidneys.*—The congestion may be active, representing the early stage of an inflammation of the kidneys, or passive, from obstruction to the outflow of blood from the renal vein. Venous congestion may be part of a general obstruction to the venous flow, and may be caused by heart disease of various kinds, emphysema, and intrathoracic tumours. On the other hand its cause may be more local, such as the pressure of tumours within the abdomen, or of ascitic fluid upon the renal veins.

4. *General Anæmia*, if of severe degree.

5. *Pregnancy and the Puerperal State.*—Although not necessarily productive of organic kidney disease, this cause of albuminuria will be fully discussed under the head of BRIGHT'S DISEASE.

6. *Certain General Blood Disorders*, such as purpura, scurvy, and septic conditions, apart from the accompanying pyrexia. In hæmoglobinuria, which is of similar origin, albumen also appears in the urine in large amount.

7. *Lead Poisoning.*—The association of albuminuria with lead-poisoning is well known. In such case it has been proved both clinically and experimentally to be accompanied by such organic disease as is found in the granular kidney of Bright's disease.

8. *Nervous Disorders.*—Grave nervous diseases, such as tetanus, delirium tremens, and cerebral hæmorrhage, are sometimes productive of a temporary albuminuria. A trace of albumen in the urine is frequently observed after an epileptic seizure, and also after mere emotional disturbance. It may be noted here that albuminuria has been experimentally produced by puncture of the floor of the fourth ventricle. Albuminuria of intermittent occurrence has been noticed in cases of Graves' disease.

9. The condition variously known as functional, simple, transient, physiological, or *cyclic albuminuria*, or albuminuria of adolescence. This will receive further mention below.

10. *Various Functional Disorders.*—Dyspepsia, a highly nitrogenous food, such as eggs, used in excessive amount, a prolonged rigor, cold bathing, the inhalation of sewer gas, excessive muscular exertion, and the blowing of wind instru-

ments have been shown to be causes of albuminuria. By whatever cause albuminuria is induced it is subject to the influence of these and other functional disturbances. Thus the albuminuria of chronic Bright's disease is often more pronounced after meals; is governed by the amount and character of the food assumed; is increased by muscular exercise and by the upright posture, while diminished and even caused to disappear by rest in bed.

Cyclic Albuminuria.—The form of albuminuria which is known perhaps the most generally by this name has received great attention in recent years. It is not uncommon to meet with albumen in the urine of persons who appear to be otherwise healthy, or who complain of but slight symptoms of disease. The state of the urine is frequently first discovered during an examination for life insurance. A large majority of the subjects of this condition are young persons of both sexes at about the age of puberty, whence one name for the condition, albuminuria of adolescence. The urine contains as a rule only a small quantity of albumen, but this is not invariably the case. It is, moreover, noted that the conditions mentioned above (section 10) as influencing all albuminurias have more effect in increasing or diminishing the quantity of albumen in this form. Thus the urine may be free from albumen before breakfast, but contain an appreciable quantity after that meal. The upright posture and muscular exertion greatly increase the amount of albumen. Frequently, too, the albumen makes its appearance only at stated times of the day, but regularly at those times, whence also its term "cyclic." The urine is seldom of a specific gravity lower than normal; its colour is sometimes deeper than usual; it may deposit crystals of uric acid or oxalate of lime, and even occasionally a few hyaline casts. The amount of urea contained in the urine is not diminished, but may be increased. Bile salts are said to be increased, and peptones or sugar have been known to alternate in appearance with the albumen. The subjects of the affection may be in apparently robust health, or they may be pale and languid, and suffer from dyspeptic disorders. The writer believes that two separate categories of these cases may be distinguished by a reference to the arterial tension. In one group there is a high arterial tension, as indicated by the condition of the radial pulse, and in such cases it is not uncommon to find a de-

posit of uric acid in the urine. Sometimes the pulse of persons of this class presents the characters of "virtual" tension, where the heart fails to entirely overcome a peripheral resistance. In the second group the pulse is that of low arterial tension, and such persons often suffer from dyspepsia and general want of tone. The nature of cyclic albuminuria is still obscure. It has been variously asserted to be due to changes in the circulation of the kidney, to atony of the vessels and nerves, to a food albuminuria, and to increased destruction of red blood-corpuscles. Probably the first is the correct view in most cases.

Pathology of Albuminuria.—It has been asserted that albumen is a normal constituent of the urine, and that its presence in disease is merely an exaggeration of the normal condition. It is true that some observers have, by evaporating normal urine *in vacuo*, obtained reactions indicating a trace of albuminous matter, but it must be assumed that when albumen is present in an amount discoverable by the reactions given above, it is the result of a pathological process. Two views have been put forward to explain the absence of albumen from normal urine. The one, that of von Wittich, assumes that albumen is actually transuded into the glomerular capsule, but is afterwards re-absorbed by the renal epithelium; the other, that of Heidenheim, which is more generally advocated, being that the albumen of the blood plasma is prevented from reaching the interior of the glomerular capsule by the layer of epithelium which covers the glomerular tuft. This epithelium has a selective secreting power, and normally eliminates water and urinary salts, but keeps back the albuminous matters. Now, an albumen may be present in the blood which is foreign to that fluid, and this is not retained by the glomerular epithelium, but may make its appearance in the urine. It has been thought that peptones, hemi-albumose, egg albumin, various physical modifications of serum albumin, and hæmoglobin may thus obtain access to the urine. This is true in some instances, but the writer is of opinion that the frequency of occurrence of such a process is exaggerated, and that often the modified albumens under discussion are the result of changes which ordinary serum albumin has undergone after being mingled with the urine. Any condition which interferes with the nutrition of the glomerular epithelium, or in certain cases, of the

renal epithelium, causes albuminuria, since the epithelium then no longer retains the blood albumen. Thus, an inflammation of the epithelium, as in parenchymatous and glomerular nephritis, is accompanied by albuminuria. But a mere functional disturbance of the epithelial nutrition will act similarly. Delay of the blood-flow from heart failure or other cause, or possibly irritation of the epithelial layer by the excretion of abnormal matters, will thus disturb its nutrition and allow the albumen to transude. Disturbance of the arterial tension probably acts upon the kidney function indirectly by influencing the circulation of blood through the capillary vessels, and so again causing disorder of the nutrition of the epithelium. Such is a concise, if not complete, account of the main views which are held as to the pathology of albuminuria; it has not been thought desirable in a practical treatise to enter into fuller details upon a theoretical question.

PROGNOSIS OF ALBUMINURIA.—Albuminuria being only a symptom, its prognosis must be the same as that of its cause. If the latter be functional, the prognosis is usually good; if organic, it is bad. The greater the quantity of albumen passed in twenty-four hours the more likely is the cause to be organic. A persistently low specific gravity of the urine and a deposit of granular, epithelial, or fatty casts are positive signs of organic kidney mischief. A few hyaline casts may be found in functional disorders, but a large number of them is indicative of more serious trouble. The writer has occasionally found that the form of albumen present in slight and unimportant albuminurias was entirely serum globulin, without admixture of serum albumin. This phenomenon, however, is not sufficiently common to be of clinical utility. The long persistence of an albuminuria is of grave omen. The prognosis of cyclic albuminuria is still in dispute. Some assert that it is of no moment; others, that it is liable to lead to organic kidney disease. Long and extensive experience is necessary to determine the latter point. The writer is of opinion that albuminuria, even when of undoubtedly functional origin, should always be considered as a diseased condition, and for purposes of life insurance be taxed, in spite of the otherwise healthy state of the system.

TREATMENT.—Like the prognosis, the treatment of albuminuria depends upon its cause. In the presence of organic

disease the symptom itself rarely requires separate attention, but this will be considered in the section on BRIGHT'S DISEASE. The writer recommends for each of the two varieties of cyclic albuminuria a different treatment. The cases in which there is high arterial tension are best treated by alkalis (such as the tartrate of soda and potash, the sulphate and phosphate of soda, or the acetate of potash) and by fairly free purgation by salines, with the occasional use of a mercurial pill. Those in which there is low arterial tension require the mineral acids, strychnine, and sometimes iron.

PEPTONURIA.—Peptones are detected in the urine by the following test:—Liquor potassæ is poured into a test-tube to the height of nearly an inch, and to it is added one or two drops of a solution of sulphate of copper, so as to make a fluid having the faintest possible blue colour. On the surface of this the urine is allowed to flow gently. A purple ring at the junction of the two fluids indicates the presence of peptones. Peptones are never present in the urine in more than small quantities, and their detection is of no practical utility.

HEMI-ALBUMOSE IN THE URINE.—This body has been found in the urine in osteo-malacia, in glycosuria, and in phthisis. It gives a precipitate with nitric acid, which is dissolved in the acid on heating, giving a bright-yellow colour. The urine on being heated becomes cloudy, but clears on further heating, the precipitate re-appearing on cooling.

MUCIN IN THE URINE.—Mucin is very frequently present in the urine. It is precipitated by the addition of citric or acetic acid. The "mucin" ring obtained by the addition of nitric acid has been already described.

ROBERT MAGUIRE.

ALCOHOL (ethylic alcohol, $C_2H_5.OH$) has not been obtained in a perfectly pure state. "Absolute alcohol," the purest form obtainable, contains from 1 to 2 per cent., and "rectified spirit" 16 per cent., of water; "proof spirit" contains 53 per cent. of alcohol by volume. The strength of the various alcoholic beverages in general use will be found under ALCOHOLIC LIQUORS.

Alcohol evaporates readily, and, when applied to the skin, carries off heat rapidly, producing a sensation of cold and causing contraction of the blood-vessels. If evaporation be prevented, as by covering the surface with a layer of oiled silk, it penetrates the epidermis

and stimulates the cutis, producing hyperæmia and a feeling of warmth. In either case the cuticle is hardened.

Applied to a mucous membrane, it causes coagulation of the mucus lying on the surface, and astringes the membrane.

In the mouth alcohol stimulates the salivary secretion. In the stomach, in small amounts, it stimulates the vascular supply of the wall, producing an increase of secretion, a feeling of warmth and appetite, and an augmentation of peristaltic movement. In large amounts alcohol checks the action of the gastric ferment, and causes irritation of the gastric mucous membrane, with consequent diminution or perversion of its secretions.

Probably from the mouth it exerts a reflex stimulus on the cranial circulation, and from the stomach a similar influence on the heart. These reflexes are with difficulty separated from the direct action of alcohol.

Alcohol is absorbed unchanged from the stomach and carried into the circulation, where it is in part destroyed, and in part excreted by the lungs. A small amount passes out in the urine. Alcohol is absorbed also from the lower bowel, and may be administered in the way of an enema.

In the blood it diminishes the oxidizing power of the hæmoglobin, and thereby lessens tissue change and waste. Alcohol acts also as a food, like sugar and other carbo-hydrates.

It causes dilatation of the vessels of the surface of the body, producing a feeling of warmth and a general flush, especially observable in the parts which are usually exposed to the air, and whose vaso-motor mechanism is therefore the most active. The pulse is quickened, and the whole circulation becomes accelerated.

Owing to the increased activity of the circulation, the cerebral functions are stimulated, producing, for a time, liveliness, alertness, mirth, and good-fellowship, with increased hardihood and power of muscular exertion. These effects are, however, but of short duration.

The action of alcohol on the circulation, causing an increased surface elimination of heat, unites with its action on the blood—whereby heat production is diminished—to lower the bodily temperature.

After a time, supposing a considerable dose to have been taken, the direct effects of alcohol on the nervous system become manifest.

The intellectual faculties are first attacked, the judgment being early im-

paired; the power of articulation is soon affected, and speech becomes "thick"; paralysis of the cerebellum produces double vision, vertigo, and staggering. Drowsiness and loss of power in the limbs follow; and if a very large dose have been taken, the respiratory centre is paralysed, sleep passes into coma, and death occurs from asphyxia. If, in animals, artificial respiration be maintained, a large dose of alcohol is found to produce death by gradual paralysis of the heart.

Very large amounts of strong alcoholic liquor rapidly ingested have been found to produce death by shock—that is to say, by a sudden reflex inhibitory action from the stomach to the heart. Persons intoxicated by alcohol are, on the other hand, remarkably exempt from the shock of severe injuries, probably owing to the paralysed condition of the reflex vaso-motor apparatus.

Alcohol appears to exercise an inhibitory action on the bowels, and a dose of strong alcoholic liquor will frequently check diarrhœa; but the nature of the action is obscure.

Large amounts of alcohol produce irritation of the stomach, causing vomiting, loss of appetite, dryness of the tongue, a feeling of intense depression, and severe general headache. The more concentrated the alcohol the greater is the irritation of the stomach. Alcoholic liquors therefore irritate less when taken with food than when imbibed on an empty stomach. Strong alcoholic liquors derange the functions of the liver, but in what manner is not clear.

The physiological action of alcohol itself is somewhat difficult to separate in practice from that of the ethers with which it is found associated in most alcoholic liquors.

The continued ingestion of alcoholic liquors in considerable amounts is liable to produce fatty infiltration of the liver, omentum, heart, and subcutaneous tissue, shrinking of the brain from partial degeneration, and thickening of its membranes. In rarer cases a degeneration of peripheral nerve fibres is found, coupled with increase of the fibrous elements of the nerves involved (*vide* PERIPHERAL NEURITIS). The habitual use of the stronger forms of alcoholic liquor leads to serious disease of the liver, involving a thickening of its fibrous elements and atrophy of its parenchyma (*vide* CIRRHOSIS).

The excessive use of alcoholic liquors predisposes, at least in the elderly, to

the development of tubercle. There is some reason to believe that in the young it checks for a time this form of growth. The development of malignant disease, there is also reason to believe, is hindered by the free use of these liquors.

The use of certain kinds of alcoholic liquors markedly predisposes to gout, and through gout to granular disease of the kidneys, but alcohol appears to have no direct pathological action on the kidneys. Intemperance has a distinct effect in the production of mania, dementia, and certain other forms of insanity. It is doubtful whether it is to any great extent a cause of general paralysis.

The effects of continued alcoholic excess, as observed clinically, apart from the more definite lesions mentioned above, are described under CHRONIC ALCOHOLISM and DELIRIUM TREMENS.

The induction of pathological lesions is the more probable the more concentrated the state in which the alcohol is introduced into the circulation. Independently of this, special forms of alcoholic liquor have a particular tendency to the production of special lesions. Those in which much alcohol is combined with sugar or much free acid, for example, tend to induce gout. Whisky and gin particularly give rise to cirrhosis; brandy is especially prone to excite delirium tremens. Some special nervous maladies are attributed to particular kinds of wine in the neighbourhoods in which those wines are grown.

That the general health is deteriorated to a marked degree by the use of alcoholic liquors beyond very moderate amounts is certain. Dr. Parkes regarded the daily consumption of an ounce and a half of alcohol as the utmost amount compatible with the maintenance of full vigour in a strong man. This would be equivalent to a pint and a half of ordinary English beer, three parts of a bottle of sound French or German wine, or three ounces of Scotch or Irish whisky. Any increase of the alcoholic habit beyond some such grade as this is attended with a progressive decline in the average longevity of the subjects of the habit. The strictly temperate in the use of alcoholic liquors would appear, on the average, to enjoy at least ten years more of life than the habitually intemperate. The shortening of life, however, caused by the *extremes* of intemperance is probably much greater than ten years.

The shortening of life due to alcohol is only in part caused by the induction

of special "alcoholic" lesions of so well marked a type as cirrhosis, gout, and peripheral neuritis. The changes wrought by the drug in the body appear to be such as to induce an increased predisposition to the attacks of disease in general. Deaths from "old age," as it is termed, without obvious pathological lesion, are far more frequent among the temperate than the intemperate.

The prevalent belief that the liability of pneumonia to a fatal issue is increased by alcoholic habits is not borne out by the statistical evidence available; nor does it appear that the intemperate are especially liable to prostatic enlargements and the vesical disorders incident to advanced life, as has been asserted. The tendency to arterial degenerations seems to be augmented by alcoholic excess, and the intemperate are more liable than the temperate to death from cerebral hæmorrhage, but not to such a degree as to justify us in considering this a specially "alcoholic" form of disease. The same may be said of degenerative diseases of the heart-wall. It is doubtful whether bronchitis is materially induced by alcoholic liquors, though the predisposition to catarrh of the upper part of the air passages is undoubtedly increased by the use of the stronger forms.

Whether the use of alcohol in the amounts specified by Dr. Parkes is really harmless, hurtful, or actually beneficial to the generality of mankind is a point which cannot at present be pronounced upon with any certainty. Statistical evidence has been adduced in abundance, from the experience of assurance and friendly societies, to establish the superior healthfulness of total abstainers as compared with the average of assured persons; but no direct comparison has yet been afforded between the general longevity of those who use alcoholic liquors in conformity with Dr. Parkes' rule and those who do without them altogether. It is clear, however, from a comparison of statistics, that any general detriment to health that may be thought to arise from total abstinence from alcohol is small in comparison with that caused by even moderate excess in its use. For the ordinary run of mankind living under fairly healthy conditions, alcoholic liquors must be regarded as luxuries, practically harmless if indulgence in them be restrained within strict bounds, but distinctly hurtful if those bounds be exceeded, and containing in themselves, for a large part of the population, a very serious temptation to excess. In condi-

tions of malnutrition, during convalescence, and in cases of scrofula and phthisis, wines and sound beers are often found to have a distinct tonic and restorative effect, but, a certain proportion of such cases and some conditions of severe illness apart, it is only exceptionally that the practical physician need insist on the use of alcoholic liquors, or hesitate to sanction their disuse if on other grounds it may seem desirable to do without them.

Medicinal Uses.—The rapid evaporation of alcohol, and its consequent power of reducing the temperature and, when applied locally, of contracting the blood-vessels of the surface of the body, is taken advantage of to relieve "nervous" headaches and to check inflammation in sprains and recent injuries. In the former case brandy, whisky, or eau-de-Cologne is either rubbed on the forehead and temples or sprayed upon them, or applied upon a piece of lint or linen, and allowed to evaporate. In the latter case a piece of lint soaked in some form of spirit is placed upon the injured part, kept constantly moist, and exposed to the air. Evaporation may be promoted by fanning.

Its power of hardening the epidermis is utilized to prevent threatened bedsores and cracks in the nipples. The part affected is simply bathed in spirit two or three times a day.

Diluted spirit is used also as an astringent wash or gargle to the mouth or throat in cases of relaxation, ulceration, and salivation, and as an application to the eyes in slight conjunctivitis.

Friction with spirit is employed as a stimulating application to the surface in cases of sluggish circulation, local chill from exposure to cold, passive œdema, chilblain, muscular pains, sprains, and chronic affections of the joints. It is similarly applied to the præcordia with the view of reflexly stimulating the heart in syncope or shock, and indeed to any part for which a mild local stimulant or counter-irritant is indicated.

A teaspoonful of strong brandy, whisky, or liqueur held in the mouth is sometimes found to relieve toothache.

Internally administered, its power of exciting the gastric functions may be utilized. In cases where, without obvious reason, the appetite fails at meal-times, a glass of light wine taken about a quarter of an hour before sitting down to table is sometimes found to arouse a desire for food. In many people a little wine taken with a meal promotes the operation of digestion, and in some weakly and aged

persons a small glass of liqueur or strong spirits taken after the meal is a needed stimulant to gastric activity. The need for alcohol as an aid to digestion is most often found in convalescents and in persons exposed to overwork and worry, especially in those engaged in a close and unhealthy atmosphere. In such cases it is difficult to separate the direct effects of the drug on the stomach from the indirect effects brought about by the promotion of cheerfulness and the relief of mental depression. The action of the alcoholic stimulant is probably complex. The physician should be careful in such cases to avoid recommending it until he has made every effort to ascertain and remove the cause of the symptoms, as few uses of alcoholic liquors have a greater tendency to lead to excess than this. In many instances a small cup of beef-tea taken shortly before a meal, or one of strong coffee, or even of hot water alone, immediately after, will succeed as well as the alcoholic stimulant, and is without its disadvantages. Ten grains of bicarbonate of sodium taken in half a wineglassful of water may replace the beef-tea, and the judicious use of pepsin or of bitter tonics may obviate the need of a stimulant altogether. It is hardly necessary to add that in a large number of such cases over-feeding is the sole cause of the symptoms. In cases of irritation of the stomach alcoholic liquors should be wholly avoided.

Wine and beer, as above stated, may be of restorative and tonic value in cases of malnutrition, especially in scrofulous and phthisical states.

Alcohol, usually in the form of brandy or other spirit more or less diluted, is constantly used to stimulate the circulation and relieve embarrassment of the heart in cases of heart disease, functional or organic, bronchitis, emphysema, and other chest affections; and to restore the circulation in syncope, shock, or chill of the surface from exposure to cold.

In the last-named case it is not safe to employ alcohol unless the body can be at the same time placed in a warmer atmosphere. The power of alcohol to restore warmth to the surface results from its property of dilating the peripheral vessels. If the surface remains exposed to cold, the blood as a whole is liable to be cooled down to a dangerous degree.

A dose of alcohol is of service in fitting the body to undergo some unusual exertion, or to withstand the shock of unusual suffering, or to resist exposure to unhealthy effluvia or zymotic contagia;

but the effects in this regard are transitory, and it is best avoided, on account of the succeeding depression of the nerve-centres, when the exertion or exposure is likely to be prolonged.

Its continuous use, however, sometimes relieves the weariness, restlessness, pain, and mental depression of chronic illness.

Alcohol is a food, not, it is true, of much value in ordinary health, but, as it requires no digestion, of great utility in some cases of severe illness or extreme senility, when the digestive functions are in abeyance, and other kinds of food are either not tolerated or not properly assimilated.

The stronger kinds of alcoholic liquors, especially brandy, are often employed with success in relieving colic and diarrhœa. The relaxation of the vessels which alcohol causes renders it of service in inducing the menstrual flow in cases of dysmenorrhœa without organic cause. In such cases it needs to be given with great caution, as the risk of temptation to excess is great. It should be prescribed in a pharmaceutical form, and not in the shape of wine or spirits.

Alcohol is employed in the treatment of fevers and febrile diseases with five objects—first, to aid the stomach in digesting food; secondly, to provide an easily assimilable form of food; thirdly, to check the excessive tissue waste of the pyrexial state and to aid in lowering temperature; fourthly, to maintain the circulation against the depressing effects of the disease; and, fifthly, to relieve weariness, restlessness, and pain.

The disadvantages of its use in these conditions are its tendency to irritate the stomach and hinder the assimilation of food, and its paralyzing effect, if large amounts are absorbed, on the respiratory centre. Irritation of the stomach will be evidenced by dryness of the tongue and decreased inclination for food; respiratory paralysis, by enfeebled action of the respiratory muscles. The use of alcohol in any given case must be governed by the balance of advantages and disadvantages.

It is certainly not required in all cases of severe fever or inflammation, and should never be prescribed as a matter of routine or without some definite object in view. If prescribed, its administration should be as carefully regulated with reference to time and quantity as that of any other drug, and its effects on the pulse, respiration, complexion, tongue, and general condition closely watched. If the pulse, respiration, and

general state improve, while the tongue remains moist and the capacity for taking food is unimpaired, the drug may be continued. If, on the other hand, the tongue becomes dry and brown and tolerance of food decreases, without any counterbalancing improvement in other respects, the alcohol is probably doing harm, and the dose should be lessened or its use abandoned. Diluted brandy or whisky are the forms of alcohol usually tolerated best in cases of fever; but some form of wine, still or sparkling, is in many cases found to agree better. As regards the amount it is impossible to lay down any rule. Much depends on the patient's previous habits, and in every case the dose must be a matter of experiment.

In prolonged convalescence alcoholic liquors may be useful in relieving the sense of tedium and weariness incidental to the condition and in stimulating the enfeebled digestive powers. In recovery from enteric fever they sometimes aid the patient in supporting the necessary abstinence from solid food.

An irritable condition of the stomach, the larynx or pharynx, or of the urinary organs is generally speaking a contra-indication to the use of alcohol. It should be avoided, for reasons given above, by persons liable to prolonged exposure to cold. In ordinary health alcoholic liquors should be taken only at meal-times, and especially avoided when the stomach is empty.

All experience goes to recommend abstinence from alcohol, as far as possible, to Europeans living in a tropical climate.

To conclude: In advising the use of alcoholic liquors the physician must constantly bear in mind the risk of exciting a taste for them which may lead to the development of the craving for drink to which probably one-third of the population of the United Kingdom are more or less liable. In doubtful cases the needed amount of alcohol may be more safely prescribed as a pharmaceutical draught than given in the form of wine or spirits.

ISAMBARD OWEN.

ALCOHOLIC LIQUORS. — The forms of alcoholic liquor in use in this country comprise wines, beers, and spirits, besides cider, perry, and liqueurs. Natural wines are the product of the fermentation of grape-juice. If the fermentation be complete and all the glucose converted, a "dry" wine results; if it be checked at a certain

point so as to leave some glucose unchanged, a "sweet" wine is obtained. "Liqueur wines" consist of grape-juice only slightly fermented and preserved from further change by added spirit. "White" wines are the product of white grapes, or of red grapes the skins of which have been excluded from the fermenting juice, or "must." If the skins of purple grapes are left in the must as it ferments, a "red" wine results. In "sparkling" wines a part of the carbonic anhydride generated in fermentation is retained in the liquid, and not allowed to escape until it is drunk. "Muscat" wines are made from grapes partially dried in the sun.

Natural wines contain, besides alcohol and water, acid tartrate of potassium, tartrates of sodium and calcium and other salts, free tartaric acid, malic and other vegetable acids in small amounts, extractive matters, a little free carbonic acid, and a number of delicate ethers formed by the action of the acids on alcohol, of which ceananthic ether is the most constant.

Sweet wines contain also a variable amount of glucose; red wines hold in solution some tannic acid and a colouring matter from the skins. Even white wines contain a trace of tannic acid.

The "strength" of wines is the proportion of alcohol they contain; the "body" depends on the amount and proper blending of the solid ingredients; the "bouquet" or perfume perceived by the nose, and the "aroma" or effect on the back of the nostrils when the wine is on the palate, are due to the ethers, and in some red wines to a volatile oil from the skins; the "savour" or taste is produced by the ethers, the acids, and the acid salts. "Roughness," or astringency, is the result of the tannic acid.

The stronger red wines, on keeping, deposit a "crust" of acid tartrate of potassium with tannic acid, colouring and extractive matter. A further development of flavouring ethers takes place when wine is kept. This is known as "maturing."

Natural wine may contain from 5 to 20 per cent. of alcohol. Practically, no wine of less alcoholic strength than 10 per cent. comes to this country. The weaker wines require the addition of so much spirit to enable them to travel by sea, and more or less spirit is added to all before the voyage. An amount of alcohol over 14 per cent. is most probably artificial.

The medicinal and pathological effects of wines depend on the alcohol, the ethers, the free acids, the tannin, the sugar, and the salts they contain.

The effects of alcohol have already been discussed. The presence of the ethers enhances its stimulant action, especially on the stomach and the brain. Hilarity is the characteristic cerebral note of intoxication by natural wine. The disengagement of gas from sparkling wine reinforces and accelerates the reflex stimulation which alcohol exerts on the brain and the circulation. The ethers have probably a pathological influence of their own on nerve structures; special nervous symptoms are locally attributed to certain wines rich in them. The acids and acid salts promote appetite, but if in excess may derange digestion. The tannin acts as a bitter tonic. The more astringent wines are apt to constipate. The salts as a whole supply some important elements of nutrition, and aid in the restorative effects of wine. An excess of tartar is apt to disorder the bowels. Wines containing a high proportion of alcohol in combination with sugar, as port, sherry, and Sauterne, or with much free acid, as Burgundy and Rhine wine, are prone to induce gout and lithiasis, and to cause digestive disturbances. Sweet wines are, of course, inadmissible in diabetes.

Most of the wine drunk in this country is supplied, or purports to be supplied, by France, Germany, Spain, and Portugal. Madeira is being re-introduced, and a few varieties of Italian and Hungarian wine have become commonly known.

Good red Bordeaux, or "claret," wines, from the district of the Gironde, are hygienically the ideal wines of the world. Moderately alcoholic (from 8 to 13 per cent. of alcohol) and completely fermented, they are of good body and well supplied with ethers, but, when properly matured, contain no excess of tartar or of tannin, and only so much free acid as is necessary to keep them from tasting "flat." They can therefore be borne by even the most delicate stomachs, and, while tonic and restorative, have little or no tendency to excite gout or lithiasis. Unfortunately, genuine claret is difficult to obtain even in Bordeaux itself, large quantities of inferior red French, Spanish, Portuguese, and Italian wine being fortified and flavoured, and sold as the produce of the Gironde. The white Bordeaux are slightly more alcoholic than the red. They are less sophisticated and less imitated. They are only slightly acid, and are well borne by the stomach. Sauterne

is made in dry and sweet varieties; Graves and Barsac are usually somewhat sweet. The sweet varieties should be avoided by the gouty.

The red Burgundy wines are more alcoholic and of greater body than the Bordeaux. They possess marked stimulant, tonic, and restorative properties, but, though fully fermented, are less suited to delicate digestions, and are prone to excite gout by reason of the amount of free acid they contain. Chablis, the best-known white Burgundy, is a perfectly "dry" wine, and not over-acid. It is less "gouty" in tendency than the red kinds.

The sparkling white wines of Champagne contain from 6 to 13 per cent. of alcohol, and more or less sugar. A part of the alcohol, and in most cases all the sugar, are artificial additions; the latter is inserted in the form of cane-sugar, but becomes altered in the direction of glucose by keeping. The acid in most champagnes is moderate in amount, but the sugar renders them unsuitable to the gouty, and apt to disagree with the stomach. The "drier" kinds are, of course, less hurtful in these respects than the sweeter. They are exhilarating wines, speedy in their action on the brain and circulation, calculated to promote temporary cheerfulness, or to supply a rapid stimulus in conditions of syncope and exhaustion, but of little restorative value.

Deleterious imitations, fabricated from inferior white wine or rhubarb-juice, abound. Similar wines, but of inferior character and much lower price, are made on the Loire, and imported under the names of "Vouvray" and "Saumur."

"Roussillon" is a sweet red wine, used as a substitute for port. Its alcohol, as it issues for sale, ranges from 11 to 16 per cent.

The white wines of the Rhine, between Mayence and Coblenz, generically known in this country as "hock," are fully fermented and rather highly alcoholic, ranging from 7 to 14 per cent., or even higher in the best class of wine. They are of good body, and possess restorative properties, but contain an excess of free acid, which renders them unsuited to the gouty or lithatic. They are extensively imitated by fermenting glucose on the lees of the real wine, and care is needed to procure them genuine.

Moselle wines are for the most part of low alcoholic percentage, and require the addition of spirit to enable them to travel

to England. Like the Rhine wines, they contain much free acid.

The sparkling "hocks" and Moselle wines resemble champagne in character, but are usually very sweet. Sparkling Moselle is flavoured with tincture of elderflower.

Port, from the upper valley of the Douro, as made for the English market, is a partially fermented wine brought up to a high alcoholic percentage (15 to 23) by the addition of brandy, and further flavoured and coloured with slightly fermented grape-juice. It is a full-bodied wine, and contains a large amount of tannin, but has little free acid, and, when new, is deficient in ethers. It is a powerful stimulant on account of the large proportion of alcohol, but its effects are not of an exhilarating character. It possesses marked tonic and nutritive properties, and the combination of alcohol and tannin renders it of service as an astringent gargle in relaxed conditions of the throat. It is a form of alcohol well suited for administration in fevers. Its "gouty" tendencies are decided, but diminish by keeping. Imitations are extensively made from red Spanish wines at Tarragona, from Roussillon and other southern French wines at Certe, and from unknown materials at Hamburg and in London.

Sherry, as made for English use in the district of Jerez de la Frontera, is an incompletely fermented white wine heavily fortified with brandy. The tartar and free acids are extracted by sulphate and carbonate of calcium (a process termed "plastering"), a large amount of sulphate of potassium, a little sulphate of calcium, and a trace of sulphuric acid being left in the wine. Further sweetening, flavouring, and colouring are effected by means of concentrated must, concentrated wine, cane-sugar, or caramel. Some of the "pale" sherries are artificially bleached by charcoal. The completed "sherry" contains from 15 to 25 per cent. of alcohol, more or less sugar or unconverted glucose, sulphates as aforesaid, no tartar, and hardly any free acid. Except in the drier varieties, the ethers are deficient. The drier varieties of sherry are more natural wines than the sweet. "Manzanillas," which possess a flavour of chamomile, are fully fermented wines, and contain little or no adventitious spirit. The "Amontillado" flavour is a special ethereal product developed by some specimens of fully fermented Jerez wines. The exhilarant power possessed by the finer dry varieties

is wanting in ordinary sherry, which, though highly stimulating in virtue of its alcohol, possesses no tonic or restorative properties. Even the dry sherries are too alcoholic to be drunk undiluted by the gouty with impunity; the sweeter kinds are as "gouty" as port, and their tendency to cause digestive disturbances, partly due to the sulphate of potassium, is strongly marked. Like port, sherry is the subject of extensive imitation. Greek wines are manufactured into sherry at Hamburg, and much Marsala is sold under the name.

The remaining wines commonly drunk in this country are the Hungarian Carlowitz, a fully fermented red wine of full body and high alcoholic strength, containing an excess of tannin and possessing marked tonic properties; the Tuscan wines sold under the name of "Chianti," which at their best closely resemble Bordeaux, though stronger and richer in tannin; Marsala, a highly alcoholic sweet white wine made in Sicily, resembling sherry in flavour; and Madeira, of which we have sweet and dry varieties. Madeira contains from 17 to 22 per cent. of alcohol, some of which, as is also the case with Marsala, is probably adventitious. It has, when new, an excess of tartar, which is deposited on keeping. The maturation of Madeira is aided by a hot climate.

Beers are fermented infusions of malted barley, rice, maize, or other grain, flavoured with hop. The "body" of beer consists of dextrin, malt-sugar, and extractives, and constitutes about 5 per cent. of its weight. English beers contain about 5 per cent. of alcohol (the stronger kinds go as high as 10 per cent.) and a little aldehyde. The continental beers brewed on the "Bavarian" system have no aldehyde and only about half the alcohol of the English. Beers contain also a little free acid, lactic, malic, gallic, and acetic, some dissolved carbonic acid, which gives the "briskness," and a small amount of salts, with bitter hop-extract and a trace of volatile oil. Porter and stout are brewed from high-dried malt, and are blackened by products resembling caramel derived from the charring. "Bottled" beers are made on the same principle as "sparkling" wines. The dextrin, maltose, &c., contained in beers are utilizable as food, and tend to adiposity. The hop extract exercises tonic properties. The light continental beers have only slightly intoxicating qualities; the English beers exercise far more effect on the brain than the foreign,

in consequence of the aldehyde they contain. This also tends to render the intoxication of a stupefying character. Beers are apt to disagree with the stomach, and have a tendency to aggravate cough. The combination of sugar and alcohol in English beers makes them unsuitable for the gouty. New beers are liable to induce oxaluria.

Spirits are strong alcoholic liquors prepared by distillation. They usually contain 45 to 60 per cent. of alcohol, but they range much higher.

Whisky is distilled from a fermented mash of malt, or malt and grain mixed. Besides alcohol and water, it contains, when new, fusel oil (chiefly amyl alcohol, with some propyl, butyl, and other alcohols), a trace of ethers, of volatile oil, of acid, and of a flavouring matter derived from the malt. On keeping, the fusel oil disappears, and a further development of ethers takes place. Whisky should be kept at least two years before being drunk. When well kept, it is the purest form of alcohol commonly in use. In good distilleries its strength is uniformly about 50 per cent. Properly diluted, it has little tendency to derange the stomach or to induce gout or lithiasis. New whisky speedily produces cerebral intoxication, tending to a furious character, and the habitual use of it is liable to lead to serious nervous disorders.

Brandy is, properly speaking, distilled from wine. It contains the vinous ethers as well as the alcohol. Its colour is due to the oak casks in which it is kept, from which it derives also a trace of tannin. The darker kinds are coloured with caramel. Inferior kinds of brandy are distilled from the lees of wine. Brandy contains no fusel oil. The presence of the ethers renders brandy a ready stimulant to the stomach, circulation, and brain, and therefore especially useful in cases of syncope, spasm, shock, arrested digestion, or diarrhoea. It is the form of alcoholic liquor commonly preferred in the treatment of fever. The cerebral intoxication it produces tends to the furious type, and its habitual excessive use is especially liable to induce delirium tremens. Brandy drinkers are also subject to relaxation of the throat and larynx, due probably to the ethers eliminated in the breath. Imitations of brandy are obtained by the fermentation of potato starch and subsequent distillation. They contain, unless very carefully prepared, a large amount of fusel oil, and are exceedingly deleterious.

Gin is distilled from fermented grain

and flavoured with oil of juniper and other aromatic substances. It is sold sweetened or unsweetened. The oil of juniper has a diuretic action. The alcoholic strength of gin is usually below 50 per cent.

Rum is distilled from molasses. It is a very strong spirit, ranging to 75 per cent. of alcohol or higher. It contains a large quantity of butyric ether, to which its peculiar flavour is due.

Cirrhosis and neuritis are more frequent among spirit drinkers than among users of wines or beers, this being due to the degree of concentration in which the former are prone to take the alcohol. Spirits have no tonic or nutritive effects beyond those of alcohol.

Liqueurs are strong spirits, sweetened with sugar and flavoured with various aromatic substances. Ethers are developed in some kinds by keeping. They can hardly be considered medicinal agents, and their pathological effects are mainly those of strong alcohol. The "absinthe" so extensively consumed in France, which is highly flavoured with oils of wormwood and anise, produces a stupefying species of intoxication and, when habitually used, giddiness, tinnitus, illusions of sight and hearing, numbness, paresis, epileptic fits, and dementia, besides the symptoms due to the alcohol.

Ciders are made by fermenting the juice of apples. In the natural state they contain less than 5 per cent. of alcohol, some sugar, and a large amount of free acid, chiefly malic. Notwithstanding the acid and sugar, their low alcoholicity renders them permissible drinks for the gouty, but they are apt to produce derangements of the stomach and bowels. They are sometimes found to be contaminated with lead from the presses employed, and to give rise to all the symptoms and lesions of saturnism.

Perry is a similar drink, of very low alcoholicity, obtained from pears. It contains much less free acid but more tannin than cider, is rather sweet, and is a harmless beverage.

Bottled cider and perry are usually more or less fortified with spirit.

ISAMBAUD OWEN.

ALCOHOLISM.—The immoderate use of alcoholic liquors, especially of the stronger kinds, is liable to produce, probably in about one person in every three of the population of the British Isles, and especially in the children of the intemperate, a craving for alcohol which partakes of the nature of an insane impulse,

and which, in its severer forms, neither reason, nor will, nor fear, nor anything short of physical restraint can control. The craving is partly gastric, partly mental, and treatment must be directed to both sources. The condition of the stomach and bowels must be carefully looked to, and the power of will assisted by maintaining the general vigour and sense of *bien-être* as much as possible. Nourishment must be given in abundance if the stomach is capable of dealing with it, and, to supply as far as may be the place of the accustomed stimulus, it should consist largely of meat and soup: beef-tea or diluted fluid extracts of meat being used as drinks. The local stimulant to the stomach may be replaced to some extent by the use of condiments, or the administration of tincture of capsicum in 10 to 20 minim doses. Ammonia will supply both a local and a general stimulant action. Alcoholic liquors should as a rule be discontinued entirely from the outset of the treatment, but at times the substitution of some light liquor, especially German beer, which is brisk and stimulating to the palate without containing much alcohol, will answer better. Perchloride of iron (20 to 25 minims of the tincture three times a day), arsenic (3 to 5 minims of liquor arsenicalis), and liq. strychninæ (5 to 10 minims), have also been found of service. In men, especially in such as are engaged in active employments, treatment is often efficacious; in women it is doubtful whether the drink craving is ever completely overcome.

Chronic Alcoholism.—Besides the craving, a train of symptoms assignable jointly to the nervous and digestive systems results from habitual intemperance. This includes sluggishness of intellect, loss of alertness, irritability, depression of spirits, perversion of the moral tone (particularly as regards truthfulness and honour), enfeeblement of will, "nervousness," a liability to be startled, and a slight muscular tremor observable in the hands, tongue, and lips, coupled with loss of appetite, nausea, vomiting of clear fluid on rising in the morning, and looseness of the bowels, four or five semi-fluid motions being passed daily without pain. The tongue becomes thickly coated and the breath offensive. The eyes are dull, bloodshot, and watery, and the face, especially the nose, is usually congested, the alcoholic dilatation of the vessels having become permanent. Spots of a sluggish acne, vulgarly called "grog-blossoms," are often present. If

the indulgence have been chiefly in spirits, the voice is frequently hoarse from irritation of the larynx by the alcohol and accompanying ethers excreted in the breath, and an irritable cough may be present from a similar affection of the pharynx and soft palate, which will be seen to be red and "velvety." More definite forms of cerebral or nerve disturbance are occasionally added—subjective sensations in the trunk or limbs, illusions of the senses, definite delusions, or transitory maniacal attacks. The symptoms may be complicated with those of the more serious alcoholic affections, commencing mania, dementia, peripheral neuritis, cirrhosis, or gout.

The first object in the *treatment* of such a case is to obtain the assimilation of food. The stomach should at the outset be cleared from adherent mucus by a brisk emetic, a table-spoonful of mustard stirred up in a pint of lukewarm water, or a scruple of ipecacuanha in powder. Five grains of blue-pill, followed by a black draught, may be given as soon as the patient recovers from the effects of the emetic, unless there be much diarrhoea. Then, without waiting further, a diet chiefly of meat, fish, eggs, and strong soups should be commenced and pushed to the limit of the gastric powers, tolerance being obtained, if necessary, by the use of bismuth and hydrocyanic acid. *Liquor strychninae*, in doses of 3 to 5 minims, or quinine in 2-grain doses, or salicin in 10-grain doses, should be commenced as soon as the stomach will bear it. An equivalent dose of tincture of *nux vomica* or of liquid extract of cinchona may be substituted if borne better, and infusion of gentian, calumba, or cascarrilla used as the vehicle. If the stomach remains irritable, a powder of the carbonates of bismuth and magnesium, 10 grains of each, should be given after each meal; or, if vomiting be present, they may be made into a mixture with a little mucilage, and 3 or 4 minims of dilute hydrocyanic acid added. Should looseness of the bowels persist, astringents will be found of less service than arsenic, which may be given in the form of liq. arsenicalis, 3 to 4 minims, three times a day, just after meals. Sleeplessness, if present, must be combated with a dose or two of chloral hydrate, or a full dose of bromide of potassium, at bedtime, or with sulphonal in doses of 15 to 30 grains. Morphine is best avoided.

The supervention of **Delirium Tremens** is the most prominent danger in a case of chronic alcoholism. In such a

case, the shock of an injury or operation, or an unusual demand on the system from overwork, sleeplessness, acute illness, or inability to take food, may induce an attack of delirium tremens.

The tremor and gastric symptoms increase, a sense of depression and dread becomes paramount, the patient grows restless, excited, and extremely irritable, and ultimately mental disturbance, varying from slight delusions to wild delirium, sets in. The delusions are in accord with the state of restlessness and apprehension from which they start. The patient is anxious to get away from wherever he may happen to be, to go and do something somewhere else, or to escape from something or somebody. He is suspicious of those around him, fancying they want to do him some injury. If in bed, he perpetually tries to get at his clothes, to be up and off. He talks incessantly and incoherently, his delusions being seldom fixed. Objects of horror and loathing appear about him, from which he tries to flee. In less materialistic days they often assumed the forms of demons, now they are more commonly rats, snakes, spiders, and monkeys. Objective sensations are sometimes present. If the delirium increase, whole scenes of restless activity may be enacted in the patient's mind and made known to his attendants by his perpetual flood of rambling talk. Usually they are dominated by the master-sense of dread, and interrupted by wild fits of terror and fury, in which, if not restrained, he will attack his attendants and try to escape at all hazards, jumping, it may be, out of a window or over the balusters. Occasionally, however, the visions partake of a cheerful and even humorous character.

The tremor is constant; the surface is pale and usually moist and clammy, the pulse large and soft or small and weak. The patient sleeps little or not at all, the tongue is coated thickly, the breath foul, and appetite is absent. The temperature is usually only slightly raised; but pyrexia, and even hyperpyrexia, may set in. The pupils are generally dilated.

If the disease be not checked, death usually takes place from exhaustion, the patient sinking into the "typhoid" state. Occasionally fatal syncope ensues.

No special post-mortem appearances, beyond those proper to alcoholism generally, are found.

Delirium tremens has been known to develop suddenly in persons previously temperate, as the consequence of a single debauch.

The *prognosis* is usually favourable, especially in first attacks; but the affection is liable to recur on comparatively slight provocation.

The indications for *treatment* are three: to restrain the patient from injuring himself or others, to procure sleep, and to support strength by the administration of food.

The patient must be put to bed and constantly watched, his efforts to get up being restrained by the commands, and, if necessary, by the hands, of his attendant. In severe cases the mechanical restraint of bandages or shackles may cause less exhaustion than the attendant's efforts, or a padded room may be made use of during the most violent stage. The medicinal treatment should be commenced, as in the case of "chronic alcoholism," by an emetic and a mercurial purge, unless there be much diarrhoea or the patient greatly exhausted. In any case solid food must be pressed upon the patient as far as the stomach will bear it, tolerance being procured, if necessary, by hydrocyanic acid, of which 4 minims may be given with a scruple of sodium bicarbonate three or four times a day, about half an hour before food is offered. If solid food cannot be borne, strong soups and eggs beaten up in milk, should be substituted, and, if vomiting persists, rectal alimentation must be resorted to.

A draught containing 15 grains of chloral hydrate and a scruple of potassium bromide should be given every four hours, or even oftener, till sleep is procured. A drachm of tincture of hyoscyamus is sometimes added with advantage, and cannabis indica, to the extent of a grain of the extract or 20 minims of the tincture, if the chloral and bromide fail by themselves. Sulphonal in doses of 15 to 30 grains has lately proved of service. Should no improvement ensue and sleep be still absent, an injection of $\frac{1}{2}$ to $\frac{1}{4}$ grain of morphia should be substituted for the bromide and chloral treatment, and repeated as required. But the use of morphia in such cases is not without risk, especially if chronic Bright's disease be present. In case of great weakness, ammonia, brandy, and ether must be given freely. The cautious inhalation of chloroform may be of service if the delirium be violent.

Except in the event of extreme weakness alcohol is better avoided altogether in the treatment of most cases of delirium tremens. In some instances, how-

ever, a moderate amount of malt liquor—*e.g.*, a pint of porter daily—seems to be beneficial.

ISAMBARD OWEN.

ALOPECIA (*Calvities*) signifies baldness, whether congenital or acquired, local or general, partial or complete. There are various clinical types of the disease, but they are not separated from one another by hard-and-fast lines. The following are those most generally recognised:—

Alopecia universalis congenita, a very rare condition, in which there is absence or arrested development of the hair follicles; the teeth, nails and, more rarely, the nipples, are badly developed. After some months or years a small quantity of hair usually appears. Congenital bald spots on persons otherwise healthy persist as such throughout life.

Alopecia universalis acquisita affects young adults of either sex after nervous shock or without ascertainable cause. The hair of the scalp, eyebrows, beard and other hairy regions falls simultaneously. Recovery, or even improvement, is quite exceptional. For treatment, *see* ALOPECIA AREATA.

Alopecia senilis is a frequent but not necessary concomitant of old age, when the skin becomes generally atrophied and the arterioles sclerosed. The hairs usually turn grey, become dry and shrivelled, and their bulbs atrophy and fall out. Baldness, as a rule, extends from the forehead backwards, or may begin at the vertex. The beard is not generally affected to the same extent as the scalp. The condition is comparatively uncommon in women, and is frequently hereditary. Treatment is unavailing.

Alopecia prematura idiopathica has clinical characters similar to alopecia senilis, but appears at an earlier period of life. The changes in the hair follicles appear to be secondary to a sclerotic process originating in the corium.

Alopecia prematura symptomatologica may be (1) the result of febrile affections, especially the exanthemata; (2) the result of disordered innervation—*e.g.*, after grief, shock, debauchery. In both forms the prognosis is hopeful; stimulating ointments or lotions materially assist constitutional treatment in hastening recovery; (3) secondary to other diseases of the scalp which impair the nutrition of the hair bulbs or destroy them by producing scars. Among the former may be cited, seborrhoea (alopecia furfuracea vel pityrodes), secondary syphilis, eczema,

psoriasis and tinea; baldness from such causes being partial and temporary. Among the latter, lupus erythematosus, kerion, favus, leprosy, and tertiary syphilis must be mentioned; baldness thus produced is complete and permanent, although generally patchy.

Alopecia areata, vel circumscripta, (Area Celsi), is pretty clearly demarcated from the previously described forms, although it has many points in common with *A. universalis acquisita*. It is characterized by the rapid formation of circumscribed, smooth, bald patches on the scalp or any other hairy part of the body, usually circular in shape and whitish in colour. The disease is very common in London, especially among anæmic, over-worked and under-fed children. Adults are also frequently affected, the eyebrows and beard being chiefly affected. The prognosis is then less favourable. The patches are commonly met with in the occipital region, behind the ears and over the parietal eminences; they often show a roughly symmetrical arrangement; their appearance is not generally preceded by any symptoms; in a considerable number of cases they are slightly pink at first, puffy and apparently infiltrated; they are usually sharply demarcated. The presence of stunted hairs at the edge, or of loose hairs outside the patch, should awaken suspicions of the case being one of tinea tonsurans, which may, under conditions of which we have no accurate knowledge, produce patches exactly like alopecia areata. Hence probably arise the differences of opinion with regard to the pathology of alopecia areata, many able observers maintaining that it is due to the presence of a vegetable parasite, of which very various forms are figured.

The following arguments may be advanced in favour of its origin as a tropho-neurosis, the result of disordered innervation:—It is sudden in its onset; it is not contagious; sensibility of the patches is sometimes markedly diminished; it may result from traumatism, or be associated with morphœa, neuralgia, megrim, or other distinctly neurotic disorders: similar patches have been known to follow the experimental division of nerves; the hair bulbs are wasted and the hairs slender at their points of exit from the follicles, not swollen and infiltrated as in parasitic diseases; anti-parasitic remedies are not more efficacious than other irritants.

In all doubtful cases the microscope must be used.

The great majority of cases, especially in young persons, recover after a variable time. Downy hairs first appear, but these frequently fall off several times before permanent recovery sets in, and the new hairs are often white; relapses are common after intervals of months, or even years.

The disease must be differentiated from tinea tonsurans, morphœa, and diseases which cause scarring of the scalp.

Treatment.—(1) *Constitutional*.—Freedom from worry or anxiety, fresh air and exercise, with nourishing food, are to be recommended. Cod-liver oil, arsenic, iron, quinine, phosphorus, and strychnine are all of value.

(2) *Local*.—Cantharides is probably the most efficacious local remedy for stimulating the growth of hair and expediting its pigmentation. The tincture may be painted over the patches night and morning, or the following lotion applied: *R* Aceti cantharidis ℥ss, glycerini ℥ij, spiritum rosmarini ad ℥viij. Corrosive sublimate in alcoholic solution, sufficiently strong to produce a rube-facient effect, may be dabbed on twice daily; *e.g.*, *R* Hydrargyri perchloridi grs. iv–viij, eau de Cologne et aquæ destillatæ aa ℥ss. Ammonia is also useful, the liquor ammonii fortioris being sometimes employed, but the following formula, which we owe to Erasmus Wilson, will be found more convenient: *R* Liquoris ammonii fortioris ℥j–℥ij, tincturæ cantharidis et tincturæ rosmarini aa ℥ij, spiritus vini rectificati ℥iv, olei amygdalæ et olei olivæ aa ℥j.

The official ointments of chrysarobin, sulphur and tar all have their partisans, especially as they meet both theories—parasitic and non-parasitic—of the causation of the disease.

Galvanism or the faradic brush is useful in some cases in which the neurotic origin is obvious, and where anæsthesia or other nerve disturbance is present. In any case it is as well to explain to the patient or his friends the tedious nature of the complaint, and the tendency to repeated relapses.

J. J. PRINGLE.

ALTERATIVES are substances which promote tissue change—*i.e.*, increase the metabolism of the tissues. They appear to make the tissues do more work, and that this may go on satisfactorily, a due supply of food and air

is necessary, a fact always to be borne in mind when prescribing this class of remedies. The most important of the alteratives are mercury, iodine, phosphorus, arsenic, and antimony. Certain vegetable alteratives—*e.g.*, sarsaparilla, sassafras, guaiacum, &c., are of exceedingly doubtful action.

AMENORRHOEA means absence of menstruation. It is physiological during pregnancy and lactation. At other times it may be the result of one of two conditions: either the menstrual bleeding does not take place—**suppression of menses**; or the blood does not escape externally—**retention of menses**.

Suppression of menses may be the result of—

(1) Constitutional disease. (a) Anæmia, and all conditions which cause anæmia, and (b) all wasting diseases, usually prevent the occurrence of the menstrual hæmorrhage. (c) Nervous conditions may suppress it, such as mental shock, anxiety, mental depression, melancholia. Probably, with these should be ranged change of residence. In all these conditions there is reason to think that suppression of menses is beneficial. The only *treatment* that should be employed is that required by the general condition causing the menstrual suppression. (d) Menstruation may also be suddenly arrested by exposure to wet or cold at the menstrual period, and the stoppage of the flow is often accompanied by pelvic pain. The *treatment* should be hot hip or foot baths, followed by rest in a warm bed; hot poultices may be applied to the hypogastrium, and, if the patient be full blooded, leeches to the groins or round the anus, or, in the case of a married woman, to the cervix uteri.

(2) The non-appearance of menstruation may be due to local conditions—*e.g.*, imperfect development of ovaries or uterus.

Imperfect development or absence of the ovaries is extremely rare, and its diagnosis so difficult as to be practically impossible. The uterus may be absent or imperfectly developed. Imperfect development of the uterus may be the result (a) of disease preventing the proper growth of the body, such as idiocy, cretinism, or wasting disease during adolescence. (b) But it may also be present in strong, well-grown women, who, in all other respects, enjoy perfect health. (c) After delivery, the involution of the uterus, which then takes place, may go on to atrophy. This is called superinvolution or puerperal atrophy of

uterus. Imperfect development or atrophy of the uterus is recognized by shortness or smallness of the body of the organ. By examining with one hand on the abdomen, and a finger of the other hand in the rectum, the uterus can be felt between the two hands. The cervix is usually normal as to size, or nearly so, while the body may be of the normal length, but not broader or thicker than the cervix, or the body may be so short that the length of the whole organ does not exceed two inches.

The *treatment* of these cases should be limited to remedying any disorder of the general health that may be present. It must be remembered that in some cases the menstrual function is established late, and that if the patient be seventeen, eighteen, nineteen, or even twenty, the uterus may yet develop. Even if it do not, the absence of menstruation is in no way detrimental to health, and the only way in which imperfect development of the uterus is injurious to the patient is in case of marriage, by the sterility which it entails. This applies also to puerperal atrophy of the uterus. The best advice that can be given the patient is to do without treatment, as by no possibility can it cause the uterus to develop. Galvanism, intra-uterine pessaries, and other irritants, have been employed for this purpose, and it is easy by such means to make the uterus bleed; but such bleeding is not menstruation, and it usually ceases with the irritation. It is true that there have been cases recorded in which treatment of this kind has been followed by the desired result; but they are so out-numbered by the failures, that it may be presumed they were cases in which the event would have been the same had no treatment been employed. Marriage is sometimes in such cases followed by the establishment of menstruation; but bearing in mind the lifelong unhappiness that may result from marrying in haste, marriage ought never to be recommended solely on account of its expected influence on health.

Retention of menses is the result of closure of some part of the genital passage below the body of the uterus. This may be due either to (1) congenital malformation or to (2) cicatrization.

(1) Congenital atresia most commonly affects the vagina, generally in its lower part, a transverse septum forming across the canal. This septum may be in the situation of the hymen, but is usually above it. There may be more than one

septum at different parts of the canal, or the vagina may be absent either entirely or through part of its extent. Congenital closure of the cervix uteri is exceedingly rare.

(2) Acquired atresia of the cervix most frequently occurs either from the use of caustics, or after amputation of the cervix. Atresia of the vagina may result from sloughing and ulceration occurring in the course of fevers, scarlatina, enteric fever, small-pox, measles, &c., or from sloughing after difficult labour, or from venereal ulceration. When, the passage being closed, menstruation has taken place, the menstrual blood accumulates behind the obstruction. During its retention changes occur in it which make it thicker and darker in colour. If the occlusion be low down in the vagina, this canal becomes distended and may form a tumour rising into the abdomen, and on the top of this tumour the uterus may be felt, the body of this organ not sharing in the dilatation. But if the atresia be situated higher up, the uterus and Fallopian tubes may become distended also. The distension of the parts usually produces pain, which occurs when fresh blood is added to that already retained—viz., at every menstrual epoch. Retention of menses is to be suspected when, together with amenorrhœa, we have a history of gradually increasing pain at the times when menstruation ought to have occurred. A history such as this should call for examination, first of the abdomen, in which, if the retention be of long standing, a tumour will be felt, then of the genital canal, to see if it be pervious. If there be a membranous vaginal septum, it will be felt as a bulging, elastic, convex swelling, which the retained blood behind it will probably make bluish in colour. If the vagina be wholly or partly absent, it will be felt to end in a cul-de-sac, and above it, by bimanual rectal examination, the tumour formed by the distended uterus will be perceived.

The *treatment* of this condition is to let out the retained blood. If the septum be membranous, this is best done by cutting through it with the Paquelin cautery-knife. If the vagina be wholly or partly absent, a new canal must be made. A sound must be passed into the urethra and a finger into the rectum. Then, with scissors or scalpel, the mucous membrane forming the bottom of the vaginal cul-de-sac must be cut through. When the cellular tissue beneath the mucous membrane has been reached, the dissection

must be carried on between the rectum and urethra with the handle of the scalpel, a spatula, or the finger-nail until the distended uterus has been reached. This must then be punctured and the fluid let out. Afterwards the opening must be prevented from closing, this is best done by a glass stem, and the new vagina must be kept patent by a vaginal rest or a glass drainage-tube. The opening by which the retained fluid is let out should always be a free one, but no pressure on the abdomen should be made to hasten the outflow. Strict antiseptic precautions should be taken. The cavity should not be washed out. The escaping fluid should be received by a large pad of dry absorbent wool applied to the vulva. This operation is not quite free from danger. The dangers are—(1) reflux of retained blood through a Fallopian tube into the abdominal cavity; (2) rupture of a Fallopian tube; (3) endometritis and the spread of inflammation along the Fallopian tube to the peritoneum; (4) decomposition of the retained fluid and septicæmia. These are best guarded against in the manner described, the important points being antiseptic care, a free opening, no pressure, no washing out. But should, subsequently, the discharge become foul, and symptoms of septic poisoning appear, the offensive discharge may then be washed away with advantage.

G. E. HERMAN.

ANÆMIA.—This term denotes the condition of a part or of the whole organism when the blood is either deficient in quantity or below the normal standard in quality—i.e., as regards its hæmoglobin. It is obvious, therefore, that the term is applicable to a great variety of conditions, according as the anæmia is local and limited, or general, affecting the whole body.

Local Anæmia—sometimes called “ischæmia”—can only be brought about in one way—viz., by mechanical interference with the blood-supply to the part. Whatever, then, causes an obstruction, transitory or permanent, to the arterial circulation in any region will produce anæmia of the district supplied by that artery. In many cases this is so transitory, owing to the free anastomotic circulation, as hardly to be worthy attention: but in other cases the lack of arterial blood is not so compensated, and the part suffers in nutrition and ultimately undergoes necrosis. Examples of transient local anæmia due to spasm of

vessels through vaso-motor stimulation are to be found in the first stage of inflammation, in the exposure of a part to cold, in the pallor of the surface induced by emotion or fright, or syncope, and notably in the condition known as Raynaud's disease. In inflammation this stage is rapidly succeeded by vascular dilatation (congestion); in exposure to cold—if long continued—by actual thrombosis; in emotional states, by the reaction due to the return to the normal. So, again, styptics, and such drugs as ergot, operate in the arrest of hæmorrhage by causing contraction of vessels and therefore of anæmia. As regards internal organs we have less certain knowledge concerning such transient anæmia; indeed, apart from the brain and spinal cord, no symptoms evince its presence, but in these organs certain transitory conditions of loss of function are attributable to anæmia. This is well seen in syncope. Anæmia may also be produced by compression of arteries or by blockage, as in thrombosis; but here, if the cause cannot be removed and there be no sufficient collateral circulation, the anæmic state passes into gangrene or necrosis (*vide* EMBOLISM: THROMBOSIS). Lastly, there may be a condition of anæmia of the surface with corresponding engorgement of internal vessels, as in the cold stage of ague, or in aortic disease, or, possibly, in Addison's disease, in the cold stage of cholera, &c.

General Anæmia is, however, the condition with which the name is most associated. It implies an alteration in the composition of the blood, due either to a diminution in its bulk or in its most important constituent—the colouring matter. The same condition—viz., a lowered proportion of hæmoglobin and therefore of the functional value of the blood as the great nutrient medium—results in either case, for in diminution of the quantity of blood (*e.g.*, from sudden and severe hæmorrhage) the actual amount of fluid is rapidly made up by absorption of water from the tissues (hydræmia), and the quality of the blood is thereby materially altered.

Forms of Anæmia may be (provisionally) dealt with under the heads of primary (essential or idiopathic) and secondary (or symptomatic). We say "provisionally" because it is hardly conceivable that the blood itself, which depends for its formation and standard composition upon the normal nutritional changes of the body, could be *primarily* diseased. At the same time it is con-

venient to retain the term "idiopathic" for those classes of disease in which there is reason to believe the fault lies with the organs concerned the most intimately with the processes of blood formation and blood destruction. Such idiopathic forms include chlorosis, pernicious anæmia, and the allied blood states of leukocythæmia and Hodgkin's disease (*q.v.*).

Causes of Anæmia.—Excluding the "idiopathic" class, we may consider the etiology of anæmia under the two heads of (1) deficient nutrient supply and (2) undue blood waste. Under the first head would be included any cause which interferes with a due supply of food material or of oxygen. The subject may be placed under circumstances of living or occupation which may deprive him of these necessities of life, and in consequence his blood composition will be lowered; or he may be the victim of derangements of the organs of digestion and assimilation, which lead to the same result. Anæmia, in its most extreme degree, is to be seen in cases of gastric cancer—a disease which may be quite latent, and in which no hæmorrhages may have occurred adequate to explain the anæmic state. Similarly, but less strikingly, it is shown in all cases of impaired digestion, functional or organic, and in diseases of the absorbent system. As regards oxygenation, there is ample evidence that exclusion from pure air (and light) is productive of a state of anæmia and debility. More obvious, and perhaps more frequent, are the causes which induce excessive loss of blood or of its essential components. Actual loss of blood from external or internal hæmorrhage is the most striking of such causes. Repeated small hæmorrhages have eventually the same effect as a single severe loss. Indeed, owing to the reparative powers, the latter may be quickly recovered from, whereas the former constitutes a more or less permanent drain and induces a chronic state of anæmia. Such latter instances are to be found in repeated attacks of intestinal hæmorrhage as from piles, or of uterine hæmorrhage, as in fibroid of the uterus, or in the repeated bleedings of the hæmophilic or scorbutic, or the insidious blood-loss due to the parasite—*anchyllostomum duodenale*. Again, long-continued suppuration and chronic albuminuria are fruitful causes of anæmia; chronic diarrhœa, continued fevers, malignant disease, tubercle, or blood poisons, as syphilis and malaria: or min-

eral poisons, as lead and mercury—all of which probably operate by destroying the corpuscular elements of the blood. Even excessive neuro-muscular activity will do the same; in fact, anything which makes a great demand on the vital powers, quickening metabolism without the compensating balance of increased nutrition. Lastly, the effects of natural evolution of the body, in its growth and decline, exhibit on each hand the operation of either insufficient supply of material to the needs of the growing organism, or a decadence and waste not made up for by the waning vital powers.

Effects of Anæmia.—When long continued, anæmia necessarily produces profound alteration in the organism, as evidenced by clinical and pathological signs. Many of these are referable to the cardiac debility induced by the effect on the heart-muscle of the impoverished blood. Experimentally, fatty degeneration of the heart has been brought about by repeated blood-lettings; and fatty degeneration—a retrograde metamorphosis of the protoplasmic elements—is a common consequence of anæmia, whether it may be brought about by defective metabolism due to the want of sufficient oxidation of tissue, or by incomplete conversion of albuminoid material. As indications of this cardiac weakness may be mentioned such symptoms as palpitation, tendency to syncope, and dyspnoea, together with the cardiac bruits and the evidence of enlargement of the left ventricle. The deficiency in hæmoglobin, and consequently lessened oxygen-holding power of the blood, accounts for the dyspnoea and probably for other symptoms also. The tendency to dropsical effusions may be mainly due to the hydræmic state of the blood. On the side of the nervous system, headache, vertigo, tinnitus, and—in cases of acute anæmia—convulsions mark the effect of impoverished blood on the cerebral circulation and nutrition. Digestion is impaired and enfeebled, and all the functions of the body are deranged. (For further detail, *vide* CHLOROSIS.)

Treatment of Anæmia.—The removal of the cause of the anæmic state is the first object. The arrest of hæmorrhage, subdual of fever, &c., and removal into pure air are thus essential. But when the cause cannot be removed, then measures have to be directed to maintain the strength and to treat the primary disease. Food should be peptonized, and, if the stomach be intolerant, nutrient enemata or suppositories may be resorted

to. Medicinally, iron and arsenic are the chief hæmatinic remedies. In acute cases the best results are obtained from transfusion, either direct of blood, or indirect of defibrinated blood, or by Nussbaum's plan of "auto-transfusion." Very good results have been gained by the injection of saline fluid into the veins, in saving from impending death. Transfusion of milk or of lamb's blood has been shown to have had injurious effects, and has been consequently abandoned.

SIDNEY COUPLAND.

ANÆMIA, PERNICIOUS.—A severe and almost invariably fatal form of progressive anæmia, the existence of which was first made known by Addison in 1855, and the pathology of which has still to be determined.

It is still a moot point whether the condition can be regarded as a distinct disease or only as the final and most serious grade of anæmia no matter how arising. For it must be borne in mind that, in certain diseases of which anæmia forms the most prominent symptom, the clinical phenomena are closely paralleled by those of this so-called "idiopathic" affection—*e.g.*, latent cancer of the stomach; and the post-mortem evidences (except those strictly due to the local and primary malady) are attributable to the persistent and progressive anæmia.

Again, there are cases—those of anchylostomiasis—which for a long time were thought to be idiopathic, but which are now known to be due to the presence of an intestinal parasite, the anchylostomum duodenale. This worm induces hæmorrhage, and consequent anæmia, which may be recovered from on expulsion of the parasite by appropriate remedies. Other intestinal parasites—*e.g.*, bothriocephalus—have of late been credited with being the cause of progressive and fatal anæmia; but obviously their *modus operandi* (if such relationship do exist) must differ from that of the bloodsucking nematode. Still, it may be fairly maintained that in all such cases, whether due to the interference with digestion and assimilation, or to continued small hæmorrhages, or to the action of intestinal parasites, the anæmic state thus brought about can only become progressive and pernicious by the entrance of another factor—a factor which in many cases seems to be introduced without any satisfactory cause, or, at any rate, apart from any of the well-

recognized causes of anæmia. Hence the endeavour to ascertain the existence of lesions in the hæmato-poietic organs adequate to account for the occurrence of this condition. At one time much attention was paid to certain changes in the bone-marrow which are undoubtedly present in many cases. It was found to be red, and full of immature forms of corpuscular elements. Then the spleen and liver were found to contain an excess of iron in their composition, and iron was even found in the urine. This character seems to be the most common in all cases of pernicious anæmia, especially as regards the liver, and the recent researches of Dr. William Hunter have gone far to place the question on a sounder basis. For, both experimentally and by examination of organs in cases of pernicious anæmia, he has shown that the condition is largely one of excessive hæmolysis; and its pronounced seat in the liver suggested the further not unreasonable hypothesis that the process is initiated by the absorption into the portal blood of ptomaines generated in the intestinal tract. It is remarkable how closely at this point such a doctrine approximates to the views of some writers upon the fæcal origin of chlorotic anæmia; and yet in very few cases does chlorosis merge into pernicious anæmia. Rather it would seem as if, pathologically speaking, chlorosis were mainly due to defective blood formation (hæmogenesis), pernicious anæmia to excessive blood destruction (hæmolysis).

The use of the term "pernicious" as descriptive of this disease (or condition) is unfortunate, but has been sanctioned by usage. It implies a malignant or invariably lethal course; although this may be true of most cases, it is not of all, and it would be a novelty in nomenclature to distinguish a disease solely by its incurability. Happily, there are cases which are undoubtedly of this category that do recover, not only temporarily, but even permanently. The alternative titles of "essential anæmia" and "idiopathic anæmia" are, however, quite as much open to criticism, since they do not discriminate between this affection and chlorosis.

Each sex would appear to be about equally liable to pernicious anæmia, although in the experience of the writer the males far outnumber the females. But abroad, especially in Zürich, the number of cases among pregnant or puerperal women seems unusually high, whereas in this country such a relation-

ship is not common. It may be that other factors, especially the mode of life and diet, play some part in accounting for this discrepancy. It is a disease of early adult life, most cases occurring between thirty and forty, but it is not unknown in youth before puberty, or in the aged.

Pernicious anæmia is for the most part insidious in onset, although there are cases where it has immediately followed a violent emotional influence or shock; and occasionally a sudden profuse hæmorrhage will leave behind it an anæmia that progressively advances in all respects like the idiopathic disease. Usually, however, its course is rather chronic than sub-acute, extending over months or even years, and the subject may or may not have been previously anæmic.

The *symptoms* of the declared disease are those of intense anæmia. Frequently vomiting and diarrhœa are early symptoms, and there may even be slight icterus, not to be confounded with the faintly icteroid tint of skin due to the profound anæmia. There is breathlessness, which in time becomes marked, even when the patient is at rest. Palpitation, vertigo, tinnitus, tendency to syncope, and other symptoms referable to the anæmic state are prominent. There is frequently marked œdema, especially in dependent parts, but the general nutrition of the body is maintained. Indeed, there is mostly a fair amount of subcutaneous fat. The cardio-vascular signs of anæmia are well marked, bruits in the precordial region being often very loud, and the jugular hum intense. Hæmorrhages, especially retinal, are common and fairly diagnostic; they may also occur subcutaneously, whilst occasionally there is bleeding from mucous surfaces—as epistaxis, hæmatemesis, menorrhagia. These hæmorrhages, which serve to intensify the anæmia, are doubtless due to the altered composition of the blood and the defective nutrition of the vessel-walls. The blood is markedly altered. Besides pronounced oligo-cythæmia—to 20 or 15 per cent. of the normal, with a proportionate reduction in the amount of the hæmoglobin—the red corpuscles are much altered. Not only do they not form rouleaux, but they exhibit numerous microcytes and misshapen forms (poikilocytes) to a degree not exhibited in any other condition. The urine is usually pale, and deficient in normal pigment, but it has been found to contain iron and an excess of indican. Albuminuria is occasionally

present. There is often marked pyrexia of irregular type.

Death occurs from exhaustion, being sometimes preceded by obstinate vomiting or by severe dyspnoea with irregular breathing of the Cheyne-Stokes type.

The *post-mortem appearances*—beyond the striking pallor of all the organs and an excess of thin limpid effusion in the serous sacs—are mainly those of fatty degeneration. This is seen to its best marked degree in the heart, of which the muscle is pale and the musculi-papillares exhibit the “tabby-cat” striation due to extreme fatty change. Similar fatty patches are to be seen in the lining membrane of the aorta and other vessels. The spleen is mostly small and bloodless; in a few cases (which have been distinguished as splenic anæmia) it may be soft, swollen, and the Malpighian bodies prominent. The liver is rather large, and exhibits often undue pigmentation combined with fatty degeneration. Its excessive contents in iron have been already noted. The kidneys are pale but otherwise normal; the lungs pale and cedematous. Petechial hæmorrhages may be seen beneath the pleura and pericardium, and in the substance of the liver and kidneys, as well as in the retinae.

The *treatment* of pernicious anæmia is not hopeful; yet undoubtedly there are cases which have presented all the symptoms of the disease, including even retinal hæmorrhages, which have been apparently cured. It may often be doubted whether the cure is permanent, for it is not an unusual feature of the affection for a temporary improvement to take place. The signs of improvement consist not only in the disappearance of pallor and of the subjective phenomena, but in the gain in corporeal richness and fading of the hæmic bruits. Besides absolute rest in bed and the administration of easily digested foods (where there is vomiting and other dyspeptic signs the food should be peptonized), the most reliance is to be placed on the administration of arsenic. This remedy may be given as Fowler's solution or in a pill of arseniate of iron by the mouth, or by means of subcutaneous injection of the former. Arsenic is the only drug that has been known to have exerted any good effect, for iron almost invariably fails. A case has been recorded of idiopathic anæmia in the adult where iron succeeded after the failure of arsenic, but this is quite exceptional. In this respect pernicious anæmia contrasts with chlorosis. It constitutes the most notable difference

between the two affections. Transfusion of blood or of saline fluid has been tried with variable result, the best results being those recorded by Quincke.

SIDNEY COUPLAND.

ANASARCA signifies the presence of serous fluid in the subcutaneous areolar tissues. When present throughout the body the person is said to have general anasarca; or if, as is probable in such circumstances, there is also effusion into the great serous cavities—*e.g.*, the peritoneum and pleura—he is said to have general dropsy. The commonest cause of general anasarca is some form of nephritis, either acute or chronic, in which case it is generally first seen and is always most marked in those parts where the skin is very loose, as beneath the eyes and in the scrotum; but general anasarca may also be met with in cases of heart disease, when it commences in the most dependent parts of the body—in the legs if the person is up, in the lower part of the back if he is confined to bed. Chronic lung diseases are sometimes attended with anasarca; in such cases there will generally be found some dilatation of the heart. In anæmia, scurvy, and after long-continued diarrhoea in children anasarca is not infrequently seen, whilst sometimes no definite cause can be found. Various views are held as to the cause of the anasarca in renal disease—(1) That it is due to the impoverishment of the blood by the loss of albumen; (2) That the deficient excretion of water by the kidneys is the main fact in its production; (3) The theory of Cohnheim, that the vessels of the skin and subcutaneous tissues become altered by the same cause which induces the disease of the kidneys. Further researches are necessary in order to determine the question. In heart disease it is, in great part at any rate, due to mechanical causes. A part affected with anasarca is always swollen; the skin is often tense and shiny, and always pits on pressure, a condition for which the term *œdema* is now reserved. Local anasarca is generally mechanical and due to obstruction to the return of blood from the part affected. Phlegmasia alba dolens, the white leg seen after parturition and in other conditions, is the most common instance of local anasarca, and is due to thrombosis of the femoral vein. In gouty subjects patches of anasarca (local œdema) are not infrequently met with, and are probably due to some vasomotor disturbance, to which cause also

may be attributed the swelling of the hands and feet seen in tetany and some other forms of nervous disease.

ANEURYSM may be defined as a local dilatation of an artery, usually containing fluid or clotted blood, or both. The older writers classified aneurysms according as they were *true* or *false*, all the coats of the vessel persisting in the former, and one or more having suffered rupture in the latter. The tendency now, however, is to regard the distinction as useless, and to confine the name *false* aneurysm to one in which the rupture of all the coats has taken place, and the effused blood is limited by the condensed tissues around the rupture, and not by any of the coats of the vessel itself. This would correspond to what has been described as the *diffused* or *consecutive* aneurysm. As regards shape, the distinction of *fusi-form* aneurysm and *sacculated* aneurysm is a convenient one. The former presents a spindle-shaped dilatation of the artery; the latter springs like a pouch or bag from its side, and communicates with it by an opening which may be relatively large or small according to circumstances.

Another variety which may be mentioned is the *dissecting* aneurysm, whose seat is primarily the aorta. Here the internal coat is ruptured, and the blood forces its way between the fibres of the middle coat and distends the outer part of it and the external coat into a kind of aneurysmal dilatation. Commencing in the aorta, it may extend into its branches, and in some cases the blood finds its way back into the artery at a lower level, and the aneurysm thus becomes a permanent channel.

The following varieties do not conform to the strict definition of aneurysm; but, inasmuch as they are called aneurysms, a brief reference to them is necessary:—

Arterio-venous Aneurysm.—This condition results from the establishment of an abnormal communication between an artery and a vein. It may occur spontaneously, but is most frequently the result of unskilful venesection, its most frequent seat being the bend of the elbow. In some cases the communication between artery and vein is direct; in others a sac intervenes. In the former case the artery is comparatively little changed, but the vein is dilated, tortuous, and pulsating. To this the name *aneurysmal varix* is given. When an actual sac exists between the vein and artery it is termed a *varicose aneurysm*.

Cirroid Aneurysm and Aneurysm by Anastomosis.—The former consists in lengthening and dilatation of a portion of an artery which becomes convoluted in the same way as a varicose vein. The arteries of the neck, the temporal, and the occipital are the vessels most commonly affected.

In aneurysm by anastomosis a large number of small arteries are involved together with veins and capillaries, the whole forming a pulsating tumour under the skin. Its favourite seat is the scalp.

Symptoms and Diagnosis.—The cardinal sign of aneurysm is a localized pulsating swelling where no such condition should be found. But there may be aneurysm in the interior of the chest where no tumour can be detected, its presence being merely inferred from its pressure effects; and, conversely, tumour and pulsation may exist apart from aneurysm, as in the case of some new growth overlying an artery and receiving a communicated pulsation from it. One chief sign is relied upon for differential diagnosis in the latter case. The aneurysmal swelling is expansile, being distended in all directions by the blood pressure; the other is not. If the artery on which an aneurysm is situated can be efficiently compressed above the tumour, the pulsation ceases, and the tumour shrinks in bulk, a contrary effect being sometimes produced by compression applied to the vessel below the tumour. On auscultation over an aneurysm a bruit is generally, but not always, heard. The remaining signs are principally those produced by the pressure of the aneurysmal swelling, as, for instance, in the case of the thoracic aorta. Pain is one of these, and it is sometimes very severe. Its exact seat depends on the direction in which the tumour extends. Dyspnoea may result from pressure on the trachea or on a bronchus; dysphagia from pressure on the oesophagus; laryngeal paralysis or laryngeal spasm from pressure on the recurrent laryngeal or pneumogastric nerve; changes in the pupils from pressure on the sympathetic.

Ætiology.—Two conditions, speaking generally, are potent factors in the causation of aneurysm—namely, weakening of the coats of the vessel and increased blood pressure. The weakening may be the result of atheroma, which is the commonest antecedent, or of syphilis. The increased blood pressure is provided by the strain of sustained physical exertion, such as may occur in those who row races; in soldiers, hampered with their

clothing and accoutrements, making forced marches; or in the case of blacksmiths using heavy hammers, or workmen who have to lift heavy weights. Alcoholism acts in both ways, inducing degeneration of the vessels and causing an increase in the force of the circulation. Gout also operates as a cause, owing to the degeneration of the arterial system which it induces. The male sex suffers from aneurysm more than the female, because the above mentioned causes of the disease are more widely operative in the male. Embolism must also be mentioned as a cause; and external violence, inducing rupture of one or more of the coats of an artery, or setting up an inflammation which weakens its wall, is another.

Morbid Anatomy and Pathology.—The inner coat of the artery, having become weakened by any of the causes above referred to, gives way, and a gradually increasing pouching of part of the vessel takes place by the distending force of the blood-stream. According as the aneurysm takes the fusiform or sacculated shape the internal coat may be found lining its whole extent, altered, indeed, but still traceable, or it may exist only in patches. The middle coat may also in great part disappear. The external coat, on the other hand, becomes thickened by inflammatory changes, and forms adhesions with surrounding structures. In the interior of the sac numerous patches of atheroma are seen causing irregularity of the surface; and generally some stratified coagula are found more or less firmly adherent to the wall of the sac—a natural effort towards spontaneous cure. The more sacculated the type of the aneurysm the more abundant is this clotting, as the blood is kept less actively in motion, and the comparative rest favours the deposit of fibrin on the roughened wall.

Prognosis.—Although spontaneous cure sometimes occurs, the progress of the disease is in the great majority of cases towards a fatal termination unless it can be effectually dealt with. The aneurysmal tumour gradually increases in size until it either bursts externally or internally, the latter the more frequently; or it brings about the fatal result by pressure on some important organ.

Treatment.—In the case of arteries which are easily accessible to surgical procedure (*e.g.*, in the limbs) the most rapid and complete method of treatment is by ligature on the proximal side of the aneurysm. But the larger internal vessels are not amenable to this mode of treat-

ment, and here rest, restricted diet (Tufnell's treatment), and iodide of potassium (in doses of grs. xx ter die, gradually increased), are the chief agents on which reliance is to be placed. These all act by reducing blood pressure, and in addition the iodide is supposed to increase the coagulability of the blood. In cases having a syphilitic ætiology it also exercises a specific effect on the arterial wall weakened by syphilitic changes. Pressure upon the vessel on the proximal side of the aneurysm has also been employed both by means of the fingers of a relay of assistants and by mechanical appliances, the circulation of blood through the sac being thus stopped and coagulation induced. Other methods of treatment are by galvano-puncture, and, in the case of aortic aneurysms, by distal ligature of vessels given off beyond the aneurysm; also by the introduction into the sac of wire or some other foreign body on which coagulation may be started. Still more recently Dr. Wm. Macewen, of Glasgow, has treated aneurysms by inserting long slender needles into the sac in such a way that they scratch its wall and cause clotting of the contained blood.

DAVID W. FINLAY.

ANGINA, a word used by the old writers to signify an affection of the throat, and applied indiscriminately to a difficulty in swallowing and a difficulty in breathing. It is synonymous with cynanche, and, like it, is now seldom employed in its original sense.

ANGINA PECTORIS is the name given to an affection of which paroxysms of agonizing pain in the cardiac region and a sense of impending death are the distinguishing features. Lesions of the heart and aorta are generally, but not invariably, present. Angina pectoris is very uncommon before the age of forty, and is of more frequent occurrence in the male than in the female sex.

Symptoms and Course.—The pain commences in the first instance with great suddenness, as the result of some slight exertion, a full meal, exposure to a cold wind, emotional excitement, &c. Subsequent attacks are very liable to arise on still slighter provocation, and may develop during sleep, or without any obvious cause. Vague premonitory sensations in the præcordial region occasionally precede an anginal seizure. Patients describe the pain as stabbing, gnawing, tearing in character, or com-

pare it to the sensations of the chest being grasped in a vice. Others say that no words can express the agony they experience. The pain is usually referred to the lower end of the sternum, or somewhat to the left of this point, more rarely to the right mammary region. As a rule the pain is not confined to the sternal region, but spreads over the front of the chest, and shoots back to the left shoulder and inner aspect of the arm, sometimes passing down to the tips of the fingers. It may also radiate to both arms, to the diaphragm, neck, and occiput, and occasionally, in cases of extreme severity, it travels down to the testes and lower extremities, and may extend to all parts of the body. In exceptional instances the pain shoots to the right arm alone, and still more rarely it commences in the left hand or arm, and spreads upwards to the præcordia. A sensation of numbness or tingling is sometimes associated with the pain when it radiates to distant parts.

Cutaneous hyperæsthesia and numbness in the region of the heart have been noted in different cases. When patients are seized with angina pectoris, they generally remain rooted in the position in which the attack surprised them, for fear of increasing the pain. In other instances they assume various postures that seem to them to give relief—*e.g.*, on all fours, leaning over the back of a chair, standing upright, &c. The sensation of dying is very characteristic of the classical type of the affection, and is probably connected with the severity of the pain. The heart's action is usually somewhat increased in frequency. The pulse may be weak, irregular, and intermittent, and occasionally becomes very infrequent. In some instances the tension of the radial pulse has been found to be distinctly increased. But, on the other hand, cases have been observed where the heart's action and the pulse have been quite unaffected. The respiration, as a rule, shows no important alteration, and there is no true dyspnoea, though a sense of oppression or suffocation is sometimes experienced. Most patients are afraid to breathe deeply, and the respiration becomes shallow and slightly hurried in consequence. In exceptional instances a full inspiration has been found to give relief.

During the paroxysm the patient may feel faint and giddy, and convulsions are stated to occur occasionally, but with rare exceptions consciousness is preserved. The skin is pale, cold, and

bedewed with a clammy sweat, and the face betrays the greatest anxiety. Eructations, flatulence, vomiting, difficulty in swallowing and phonation, and a constant desire to micturate are occasional accompaniments of angina pectoris, and the termination of the attack may be marked by the passage of a large quantity of limpid urine. The paroxysm usually ends as suddenly as it begins, but at times it passes off more gradually. Anginal seizures may last a few seconds or minutes, or they may be prolonged for half an hour or even longer, and in such cases they probably consist of a succession of paroxysms.

The severity of the pain varies greatly in different attacks. At times a brief spasm of pain may alone be felt, whereas on another occasion the agony may be so intense that it leaves behind it a state of profound exhaustion. The patient may die in the first attack, or he may recover and remain free for years, and, it is said, for the rest of his life. Far more often the paroxysms show a tendency to recurrence, the pain becoming more severe, and the attacks more frequent. During the intervals the patient is free from anginal symptoms, and, except in those cases where organic disease is present, there may be no derangement of the general health.

Angina pectoris is very liable to end fatally. In a relatively large proportion of cases death occurs suddenly during an attack, but, according to Balfour, gradual failure of the circulation is the more usual mode of termination.

The account that has just been given deals with the classical type of angina pectoris, depicted by Heberden and Latham, in which a fatal termination within a few years is the rule and not the exception. Some writers, especially in Germany and France, use the term in a wider sense, and include a somewhat different class of cases, which, however, in point of symptoms resemble the classical form very closely. The pain is less severe, the tendency to radiation is less pronounced, and there is not, as a rule, the same overwhelming sense of approaching death.

This variety, described as "pseudo-angina" by Walshe and others, occurs in young persons, and especially in anæmic or neurotic females. Moreover, in these cases there is no organic cardiovascular disease, and there is little or no tendency to a fatal issue.

The "angina pectoris vasomotoria" of Landois and Nothnagel requires a brief

notice. In this affection the attack is usually attributed to cold, and begins with pain, numbness, and coldness of the extremities, followed by a sense of oppression and palpitation, dull pain in the cardiac region, which may spread over the left side of the thorax to the arm, pallor of the face, cyanosis of the fingers and toes, and cold clammy perspiration. The action of the heart is at times excited, and the pulse is small and tense. A sense of anxiety or apprehension may be experienced, but this symptom is usually a subordinate one, and no danger to life is to be feared. The paroxysms are relieved by friction, and by the application of warmth to the extremities. It is doubtful whether this disorder really deserves the name of angina pectoris. At the same time it shows that a peripheral vaso-motor spasm may give rise to a certain amount of cardiac pain, if not to the characteristic agony of a true anginal seizure.

Pathology.—Morbid anatomy throws a somewhat uncertain light on the pathology of angina pectoris. The heart is generally in a flaccid, uncontracted, or dilated state, and may present various structural changes in its walls or valves. The most frequent lesion is atheroma of the coronary arteries, or of the root of the aorta, involving the orifices of the coronary arteries. Fatty and other degenerative changes, atrophy and dilatation of the heart, aneurysm or dilatation of the arch of the aorta, and disease of the aortic valves have all been found in different cases, but no single lesion has been constantly present. A marked degree of hypertrophy is rarely met with. Walshe says that he has never known angina to occur in association with mitral disease. In a few instances anatomical changes have been detected in the nerves forming the cardiac plexus. It is said that in some fatal cases the heart and arteries have been free from disease.

The importance of these morbid conditions is somewhat difficult to estimate.

Atheroma of the coronary arteries is a very common disease, and the same may be said of the other lesions that have been mentioned, but it is only in very few instances that they are complicated by angina. It is clear, therefore, that none of these conditions alone can account for an attack of angina pectoris.

The paroxysmal and capricious nature of the affection, the suddenness with which the pain begins and ceases, the development of an attack in response to such slight reflex impulses as the act of

swallowing a draught of cold water, and the characteristic radiation of the pain are facts highly suggestive of a nervous origin. Trousseau, indeed, regarded angina pectoris as an epileptiform neuralgia. But, although no explanation is possible without invoking the influence of the nervous system, it appears that angina pectoris, in its severe form at least, is not a pure neurosis, but is rather a neurosis grafted upon an organic basis.

Heberden's original idea that the affection is due to a spasm of the heart is inconsistent with that author's statement that the pulse is unaffected, and with the relaxed condition of the heart so generally found after death. It has been suggested that the pain is the result of the strain to which the heart is subjected in its attempts to overcome increased peripheral resistance. But the sudden onset of the attack, without previous signs of cardiac derangement, and the absence of any excessive action of the heart, seem to negative the idea of an acute distension of the heart.

This explanation has been adopted by Nothnagel, with good reason, for his cases of angina pectoris vasomotoria, in which the cardiac symptoms are clearly secondary and subordinate to the peripheral vaso-motor spasm.

Brunton's observations show that in some cases the arterial tension is increased at the commencement of an anginal attack, the rise in blood pressure being due, in his opinion, to widespread vaso-motor spasm. The signal relief which he obtained by means of nitrite of amyl, which dilates the small vessels and reduces arterial tension, affords a strong support to his views as to the important influence of blood pressure in determining a paroxysm of angina. What causes the irritation of the vaso-motor nervous system on which the increased arterial tension is believed to depend has not yet been ascertained. Subsequent experience has fully confirmed Brunton's estimate of the great efficacy of nitrite of amyl in the treatment of anginal attacks, although it does not afford relief in all cases.

The manner in which vaso-motor spasm and high arterial tension induce a paroxysm of angina is not very clear. The increased intra-cardiac pressure which results from a rise of blood pressure cannot alone be the cause of the seizure, nor is it easy to see how a spasm of the coronary arterioles, if such there be, can produce such an effect. On the other hand, it is quite possible that both

conditions may precipitate an attack in certain impressionable states of the cardiac nerves.

Balfour holds that a defective supply of blood to the myo-cardium is a potent element in the causation of cardiac pain and angina pectoris. Obstructive disease of the coronary arteries and spasmodic contraction of those vessels would equally tend to produce anæmia of the cardiac walls, and would therefore act as predisposing causes.

From the proximity of the cardiac plexus to the arch of the aorta, and from the distribution of the coronary plexus in the course of the corresponding arteries, the cardiac nerves are liable to become implicated in morbid processes affecting the walls of these vessels and this circumstance has been thought to have some bearing on the pathology of angina.

On the whole, it seems probable that the essential element of a paroxysm consists in some abnormal condition of the cardiac plexus: in other words, that angina pectoris is a neurosis or cardiac neuralgia, but that vaso-motor spasm is very frequently connected with the development of an attack in some manner not as yet understood.

This view would admit the existence of a close relationship between the severe organic form and the functional or false angina. The fact that the danger to life differs widely in the two varieties is not incompatible with their essential unity, for degenerative changes in the heart's walls and insufficient coronary circulation may well account for the greater danger of a paroxysm in the organic form, the shock caused by the intensity of the pain being more likely to cause fatal inhibitory arrest of the heart's action when the organ is structurally unsound.

The characteristic radiation of anginal pain is to be explained by the numerous connections of the cardiac nerves with the brachial plexus and with the upper four cervical nerves. The tendency of the pain to spread to the left arm by preference is not easy to account for, as the cardiac plexus derives branches from both sides of the body.

The *ætiology* of angina pectoris is extremely obscure. The influence ascribed to gout and various other diseases does not seem to rest on very strong evidence. The greater proclivity of the upper classes to angina has probably been over-stated by some writers. Some cases of the functional variety occurring in

young men have been traceable to the abuse of tobacco.

Diagnosis.—The diagnosis of the severe classical type of angina presents little difficulty. The character and localization of the pain, its sudden onset and disappearance, its tendency to radiate to the left shoulder and arm, and the sense of impending death constitute a group of symptoms that can hardly be mistaken. If, at the same time, the patient be above the age of forty, and present evidence of organic disease of the heart or aorta, a positive diagnosis may be given. The absence of signs of cardiovascular disease must not prevent us from diagnosing angina pectoris in a person past middle life, for the detection of coronary or myo-cardiac disease is often quite impossible.

Attention should be particularly directed to the age, and in a less degree to the sex of the patient. It must, however, be remembered that the severe type of angina may occasionally occur in young persons, as shown by the fact that a patient of Balfour's, a young man of twenty-four, died suddenly in an attack, and the diagnosis of atheromatous obstruction of the coronary arteries was confirmed at the necropsy.

The recognition of pseudo-angina is not always easy, though the age and sex of the patient and the character of the paroxysm will often enable us to make a correct diagnosis. It is of great importance to distinguish the organic from the functional form of angina; but in some cases this is impossible, and fallacies are especially likely to arise in the case of attacks occurring in women about the period of the climacteric.

Prognosis.—The prognosis of the organic variety is decidedly unfavourable, though in such cases life may occasionally be prolonged for years. Where there is reason to believe that the symptoms are due to pseudo-angina the prognosis is favourable as regards the duration of life; but in no case should a too sanguine opinion be expressed, in view of the difficulty of distinguishing the organic from the functional form under certain circumstances.

Treatment.—For the actual paroxysm, nitrite of amyl, as recommended by Brunton, gives the most prompt results in most cases. Glass capsules, containing a few drops of the drug, should be broken in a handkerchief, and the vapour should be inhaled until relief is obtained. Nitro-glycerine, introduced by Murrell, is another valuable remedy,

and may be given internally in doses of 1 minim of a 100 per cent. alcoholic solution three or four times a day, or oftener, the quantity being gradually and cautiously increased if necessary. Nitro-glycerine may also be conveniently exhibited in the form of tablets. The combination of nitro-glycerine with ether and ammonia gives good results where the heart's action is weak; in other cases the drug may be advantageously prescribed with peppermint if flatulence be a troublesome symptom. Nitrite of sodium is believed to act in the same way as nitro-glycerine. The inhalation of amyl-nitrite generally gives the speediest relief, but a regular course of nitro-glycerine not infrequently renders other measures unnecessary. The administration of this remedy in small doses frequently repeated is generally to be preferred to the use of large doses at longer intervals. In severe cases the patient should always carry about with him some capsules of amyl-nitrite. The good effects of the nitrites are not confined to the severe organic form of angina, but are manifested in some cases of the functional variety also.

Where these remedies fail, Balfour recommends the inhalation of chloroform followed by a hypodermic injection of morphia. Numerous other medicines have been advocated, but arsenic and iodides are, perhaps, the only ones that appear to have much effect, and these drugs are greatly inferior in their action to the nitrites or morphia. The application of the constant current to the sternum has proved successful in a few instances, but electrical treatment would only be justifiable in the comparatively rare cases in which we can exclude organic disease. The general treatment of angina pectoris consists in the avoidance of everything that may predispose to an attack, such as exertion, emotional excitement, digestive disturbances, cold, &c. Regulation of the bowels is of great moment, as paroxysms of angina are not infrequently excited by straining at stool. Iron, strychnine, arsenic, and remedies directed to the improvement of the digestion will be useful in suitable cases. The meals should not be large, and should consist of light, digestible food. Rest, both of mind and body, is an essential element in the treatment. The abuse of tobacco must be avoided. Anæmia and disorders of the nervous system must be dealt with on general principles.

PERCY KIDD.

ANODYNES are remedies, acting through the medium of the nervous system, which relieve or allay pain. The chief of these is opium, including the various preparations made from it or its alkaloid, morphia. Amongst the others are cannabis indica, belladonna, hyoscyamus, stramonium, conium, veratrum, lupulus, gelsemium, bromide of potassium hydrate of chloral, chloroform, ether and camphor.

ANOREXIA signifies loss or impairment of appetite, and is met with in many forms of gastric disorder, as well as in most febrile affections and in chronic disease.

ANOREXIA NERVOSA (*Apepsia Nervosa vel Hysterica*), a condition characterized chiefly by extreme emaciation, owing to abstinence from food, and occurring chiefly in neurotic females between the ages of sixteen and twenty-three, but occasionally met with in males at about the same period of life. It was first clearly described by Laségue in 1873. Sir William Gull about the same time also drew attention to the disease (*Clin. Soc. Trans.*, 1874), and ascribed it to a "failure of power of the gastric branches of the vagus." Anorexia nervosa has close relations with hysteria and neurasthenia.

Symptoms.—The patient becomes fearfully emaciated, the eyes sunken, the skin cold and of a sallow tint; there is no desire for food, and but little is taken except upon compulsion. The mind is not weakened; there is no craving for sympathy, rather an inclination to reserve and seclusion; the mental state is one of "inexhaustible optimism" (Laségue), with restlessness and a marked desire for walking exercise and capacity for undertaking it without apparent fatigue.

The pulse and respiration are slow; there is generally obstinate constipation, and in women amenorrhœa and an arrest of fecundity. Gastralgia, vomiting, and hæmatemesis may be present.

The *prognosis* is generally favourable, but some cases have terminated fatally from extreme inanition.

No changes have been found in the stomach or elsewhere which throw any light upon the pathology of the condition.

The *diagnosis* from gastric ulcer, cancer, or abdominal tuberculosis is in many cases most difficult.

Treatment.—The patient should be removed from the care of sympathizing

friends, and a trial given to the Weir Mitchell treatment (seclusion, massage, and excessive feeding). Most cases recover so soon as they begin to take food. No drugs have been found of much use.

ANOSMIA is loss of the sense of smell—either uni-lateral or bi-lateral. It may be due to local disease affecting the mucous membrane of the nose, to injury or disease of the fifth or olfactory nerves, to disease involving the inner and lower parts of one or both anterior lobes of the brain, the olfactory bulbs, the under surfaces of the temporo-sphenoidal lobes (Ferrier), or part of a hemi-anæsthesia of either organic or hysterical origin. When anosmia is complete, taste, except for bitter, sweet, sour, and salt substances, is also lost.

ANTACIDS are given to correct excessive acidity of the stomach, whether due to the secretion of too abundant or too acid a juice, as in acute dyspepsia, or to the decomposition of food from impaired digestion. They are usually given after meals. The alkalies and their carbonates are the chief antacids, soda salts being preferable to potash, but when there is diarrhœa the lime salts should be used.

ANTHELMINTICS are of two kinds, those which simply expel the worms (vermifuge)—to which class almost all the purgatives belong, scammony and jalap being the most popular—and those which kill the worm (vermicide). Male fern, pomegranate root, kamela, koussou, turpentine, and tannate of pelletierene are all used against tape-worms. Santonin acts especially on round worms, whilst thread-worms are best destroyed by small injections into the rectum of salt and water or infusion of quassia; the latter, in combination with iron, may also be given by the mouth.

ANTIMONY, Poisoning by.—The chloride of antimony, or butter of antimony, is a violent irritant poison, but one very rarely taken. The potassio-antimonio-tartrate, or tartar emetic, is the better known. It produces a metallic taste, followed by a whitish appearance of the mouth, nausea, vomiting, and purging, with pain in the abdomen, heat and constriction of the throat, cramps in the limbs, cold sweats, great faintness, and weakness; the pulse becomes very feeble, the eyes sunken, and the voice reduced

to a whisper; death may ensue from exhaustion with or without convulsions. There are no remissions, and the general depression is greater than in arsenical poisoning, to which otherwise the symptoms have much resemblance. If small and repeated doses of the poison have been given there will be vomiting and distension of the abdomen, purging, and perhaps blood in the motions; a pustular eruption occasionally appears.

Post-mortem Appearances.—The contents of the stomach and intestines present a white or yellowish pasty appearance, and the mucous membrane may be more or less inflamed. The large intestine may be affected even when the small is found healthy; the liver may be fatty; the blood is generally fluid.

Treatment.—The stomach should be thoroughly washed out with the stomach-pump and vomiting encouraged in every way; milk and water should be freely administered; astringent infusions—*e.g.*, tannic acid (gr. 30) in solution—may be given as antidotes; strong coffee and ammonia are useful if there be collapse.

ANTIPERIODICS check or cut short the attacks of those diseases which tend to recur in paroxysms. The various forms of intermittent fever due to malaria constitute the chief class, but certain kinds of headache and neuralgia must also be included. Cinchona bark and its alkaloids, especially quinine, are by far the most important of the antiperiodics. Salicin, salicylic acid, and arsenic are also used.

ANTISPASMODICS are used to relieve or prevent spasm. The diseases which call for this class of remedies are most varied. Convulsions, laryngismus, asthma, angina pectoris, hiccup, dyspepsia, colic, hysteria, are instances. Antispasmodics may produce their effects either by direct local action or through the medullary centres. Bromide of potassium is the most important. The other bromides, opium, belladonna, stramonium, Indian hemp, ether, alcohol, nitrite of amyl, musk, valerian, assafoetida, camphor, and the volatile oils are also useful in various disorders, on reference to which the appropriate remedies and their doses will be found.

AORTA, DISEASES OF THE.—The aorta is specially liable to several of the diseases of an inflammatory and degenerative kind which are described in the article on diseases of the arteries—

namely, acute and chronic endarteritis, fatty degeneration, and calcification (*see* ARTERIES, DISEASES OF). In addition may be now mentioned stenosis of the aorta, simple dilatation and aneurysm, the last named being, of course, by far the most important.

Stenosis.—Stenosis, or narrowing of the aorta, also called *coarctation*, may be either a congenital malformation or an acquired condition. In the former case the narrowing is found close to the point where the vessel is joined by the ductus arteriosus. The amount of narrowing may be trifling, but if considerable the aorta and its branches on the proximal side are greatly enlarged. Beyond the narrowing, the vessel may be either of normal size or formed by vessels smaller than natural. The circulation is carried on by collateral channels, which become greatly increased in size. The enlargement of the vessels about the root of the neck, together with a murmur over the aorta, may suggest a correct diagnosis; but the condition is generally discovered only on the post-mortem table. In cases where the stenosis is acquired, it results from the thickening and projection into the lumen of the aorta of atheromatous or calcareous patches, which may be covered with thrombi.

Simple Dilatation.—This condition occurs chiefly in the subjects of chronic interstitial nephritis. It is caused by the extra strain thrown upon the aorta by the resistance to the circulation in the peripheral vessels, and the increase in force of the impact of blood against the wall of the artery resulting from consequent hypertrophy of the left ventricle. It is also found in cases of incompetence of the aortic valve, the force of the current of blood propelled by the hypertrophied left ventricle being alone sufficient to cause it in this case. The ascending portion of the vessel is the part principally affected. In some cases it is possible to make out by percussion that the aorta is dilated, and the second sound in the aortic area is usually accentuated and of a ringing character.

Aneurysm.—Aneurysm of the aorta is a localized dilatation of the artery. The dilated part, called the sac, contains during life either fluid or clotted blood, sometimes both. Aortic aneurysms may be divided into two classes according as they are situated in the thoracic or abdominal portion of the vessel. A further convenient division is made, in the case

of the thoracic aorta, into aneurysms affecting the ascending, the transverse, and the descending portions respectively.

As regards anatomical characteristics, the principal forms are the sacculated and the fusiform, and it is the former which contains coagulum, the circulation through the other being too rapid to permit the deposit of fibrin on its walls. A fusiform aneurysm may, however, also become in part sacculated, so that both conditions may co-exist in a given case. Other varieties will be found referred to in the article on ANEURYSM. One of these may be mentioned here—namely, the *varicose aneurysm*, in which a communication is found between the aorta and the vena cava, pulmonary artery, or one of the chambers of the heart. This kind begins as an aneurysm of the aorta, and, by pressure against one or other of the parts named, adhesive inflammation is set up, and then a perforation of the wall of each establishes a communication between them.

SYMPTOMS AND DIAGNOSIS.—I. *Thoracic Aorta.*—A. *Ascending Portion, Aneurysm of.*—This is generally the most easily recognizable form of aortic aneurysm, at least when it has progressed to any extent. There is one exception to this rule, however—namely in the case of aneurysm situated in the sinuses of Valsalva, which causes, from its position, no signs distinguishable from those of aortic valvular disease. It never reaches a size sufficient to produce an obvious tumour, and it causes death by rupture into the pericardium. In the more usual seat, higher up the vessel, the aneurysm presses forwards toward the chest-wall, and soon appears to the right of the sternum, about the second and third costal cartilages and interspaces, as an expansile pulsating tumour. Palpation may show that erosion of one or more of the cartilages from pressure of the tumour has taken place, and a thrill, systolic or diastolic, or both, may be felt. The swelling is dull to percussion, and the dulness may shade off to a considerable distance in all directions from the seat of maximum pulsation. On auscultation a systolic murmur is usually heard, and often a diastolic murmur also. The existence of the latter, especially if traced downwards to the heart's apex, is almost invariably indicative of aortic regurgitation. When the aneurysm is situated but a short distance from the valve, it is easy to see how naturally the distension of the

vessel will cause a stretching of the aortic orifice and lead to incompetence of the valve. Pain is always complained of, it may be felt in the neighbourhood of the tumour, or radiating over the chest and down the arms, particularly the right, or shooting through to the back. In this form of aneurysm, owing to the direction in which, for the most part, the tumour progresses—namely, forwards—interference with respiration and swallowing, or paralysis of the vocal cords—symptoms so frequently present with the variety next to be described—are conspicuously absent. There may be œdema, however, of the right arm from interference with the venous circulation, and shooting pain from pressure on the brachial plexus is not uncommon.

B. Transverse Portion, Aneurysm of.—When this part of the aorta is the seat of aneurysm, the signs may be less obvious. Sometimes no distinct pulsation can be made out, and there may be no decided impairment of resonance over the upper part of the sternum. On the other hand, there may be well-marked pulsation and dulness, the surface of the chest at the second left cartilage and interspace being a favourite point for their manifestation. A double murmur, or a systolic murmur only, may be present, or there may be none. Even in the last-mentioned case, however, the sounds are not normal. The systolic sound has a booming quality, which it is difficult to describe. It has been called a “thud” or “shock sound.” The second sound has a ringing or metallic quality, and is accentuated, provided that the aortic valves be competent. Pulsation also may be felt in the episternal notch.

Pressure signs are usually well pronounced. Pain is experienced, as in the case of aneurysm of the ascending aorta, and is chiefly due to erosion of the sternum and rib cartilages and to pressure on the intercostal nerves. Dyspnoea, which is often very distressing, results directly from pressure on the trachea or bronchus, and indirectly from involvement of the pneumogastric nerve, causing spasm or paralysis of laryngeal muscles; aphonia from the same cause may also be present. Pressure on the pneumogastric and pulmonary plexus or on a bronchus may set up a form of pneumonia. Cough is always present more or less, and is of a ringing, brassy, or hoarse character. Dysphagia from pressure on the œsophagus is another symptom which may be present. Pressure on the sympathetic causes in the first instance dilatation of the pupil

from irritation, and later, when the pressure is more complete, contraction takes place, from paralysis. Pressure upon venous trunks causes engorgement, cyanosis and œdema, and a clue may be found to the particular part of the aorta affected by the distribution of these signs. Some difference in the radial pulses is often found. This may be a pressure effect, the aneurysm compressing the subclavian artery, or it may occur from partial occlusion of the mouth of the innominate or left subclavian by patches of atheroma or calcification, or from the loss of elasticity of the affected portion of the aorta. The thoracic duct has also been found to suffer from pressure, but this is not common; malnutrition would be its only indication.

C. Descending Portion, Aneurysm of.—The further the aneurysm is situated from the ascending portion of the vessel the more difficult does the diagnosis become. Pain will be present, and may be referred chiefly to the back, owing to erosion of vertebræ and involvement of intercostal nerves. It is often aggravated by movement. There may be obvious pulsation in the space between the scapula and spinal column, and a murmur may be heard in the same region. Most of the other pressure signs enumerated in the last section will probably be wanting, but the bronchus and lung are likely to suffer from pressure. Aneurysms in this situation are often very obscure, and may not even give rise to such symptoms as bring the patient under the notice of a medical man at all. The writer had his attention called to a case where death occurred suddenly in the street from profuse hæmatemesis. Post-mortem, the cause was found to be an aneurysm of the descending aorta, which had ruptured into the œsophagus. It was too small to have produced any decided symptoms during life.

There are certain diseased conditions liable to be mistaken for aneurysm of the thoracic aorta which may be mentioned. They are mainly two—(1) Pulsating empyema, a very rare condition, which, if other means of diagnosis fail, may require an exploratory puncture for its demonstration; and (2) malignant growth overlying the aorta or heart, possibly forming an obvious tumour, and transmitting a pulsation to the chest-wall. In such a case the presence of cachexia and of enlarged glands will assist the differential diagnosis, and also the fact that the pulsation is not distensible, and that the auscultatory signs do not correspond

with those of aneurysm. The results of treatment may also help somewhat. In the case of aneurysm the tumour may decrease in size, the amount of pulsation may diminish, and pain may abate, but no such favourable changes will occur in the case of a growth.

II. *Abdominal Aorta*.—As regards this part of the aorta the same points *mutatis mutandis* have to be considered. The absence of the bony casing which encompasses the thorax renders, in some respects, an aneurysm here more easy of exploration. On the other hand, there is less evidence to be got from pressure signs; often, indeed, none at all except such as expresses itself in pain. The seat of the aneurysm is most commonly the upper part close to or involving the celiac axis. The first, and sometimes the only, symptom is pain in the back, which is aggravated on movement; it may shoot through from the back to any part of the abdomen, or down the loins and thighs. Constipation and dyspeptic symptoms are often present. Tumour and expansile pulsation are found in the course of the vessel, generally in the epigastric region and to the left of the middle line. If the tumour press backwards, abnormal pulsation, and possibly a bruit, may be detected in the loin. A systolic murmur may be heard in front, or there may be none. In a very few cases a diastolic bruit has been reported. Two other diseased conditions, both of which may very closely simulate aneurysm of the abdominal aorta, may be confounded with it. The one is pulsating aorta, mostly, although not exclusively, found in neurotic females. Here the pulsation is not expansile, and there is, properly speaking, no tumour; nor is a bruit heard, as a rule, with moderate pressure of the stethoscope. The other is tumour of some other part, overlying the aorta and receiving pulsation from it. Here also the pulsation is not expansile, and, as the disease is most likely to have its seat in the stomach, there will be special symptoms referable to that organ, such as vomiting. A method of inter-diagnosis usually recommended is to place the patient on his hands and knees, when, if the pulsation be aneurysmal, it will still be felt; if communicated through an overlying growth, it will disappear, owing to the latter falling away from the vessel. It is always well to investigate this point, but the result is not absolutely conclusive. (See ABDOMINAL TUMOURS, DIAGNOSIS OF.)

ETIOLOGY AND PATHOLOGY.—The essential preliminary to the formation

of an aneurysm of the aorta is a weakening of some part of the wall of the vessel. This is most frequently the result of atheroma. Given this localized weakness, any strain, such as lifting a heavy weight, may provide the immediate cause. The history of persons suffering from aortic aneurysm so frequently shows a syphilitic taint that syphilis must be admitted to be a frequent cause of the disease. Gout also has a considerable influence; so has intemperance. As might be expected from the foregoing considerations, the incidence of aortic aneurysm is much more on males than on females, the former being more commonly employed in heavy bodily labour. As regards age, the disease is mainly one of the prime of life, most cases occurring between the ages of forty and fifty. The size of aortic aneurysms varies very much. It depends greatly on the direction in which progressive enlargement takes place, implicating, or not, important structures. And there is, no doubt, an individual element also to be taken into consideration. The sac is generally, if irregular in shape and not of the fusiform kind, found to contain laminated clot, which may be tolerably firmly adherent to the wall of the vessel. It commences as a deposit on the arterial wall, which has been rendered rough by atheroma or calcification, and, in the case of the typically saccular aneurysm, it may go on till the sac is filled up and the aneurysm obliterated, a spontaneous cure taking place. In any case the sac will be seen to be the seat of numerous patches of atheroma. If a fatal result has occurred through rupture of the sac internally, the effused blood will form a tumour external to the aneurysm, or it will be found in one of the cavities of the body, such as the pericardium, pleura, or peritoneum.

PROGNOSIS.—This is ultimately very unfavourable, although life may be prolonged for years after the signs of aortic aneurysm have become well marked; and it must be remembered that the disease may exist long before it is discoverable, for it is only when the dilatation of the vessel reaches a certain size that symptoms or physical signs are produced. Important elements in the prognosis are the age of the patient, and the condition of his arteries, the presence or absence of gout or kidney disease, and the general habits past and present. When the case proceeds to a fatal issue the immediate cause of death is frequently rupture of the sac, its contents

escaping into the pleura, pericardium, right chambers of the heart, large vessels in the neighbourhood of the heart, bronchi, or œsophagus. Comparatively rarely the aneurysm bursts externally. Other immediate causes of death are exhaustion from pain and want of sleep, suffocation from pressure of the aneurysm on the trachea, a low form of pneumonia associated with occlusion of a bronchus, starvation from pressure on the œsophagus, and syncope from consecutive degeneration of the heart muscle. The last is seen in cases where the aortic valve has been incompetent. Some intercurrent disease may also cut short the patient's life.

TREATMENT.—The treatment of aneurysm of the aorta must be considered from two aspects, the medical and the surgical, the object in both being to induce coagulation of the blood in the aneurysmal sac. In the case of medical treatment this is sought to be accomplished by retarding the circulation and reducing the tension in the aneurysm; in the other the same end is attempted to be gained by more direct means. As regards the former, rest in the recumbent position, careful dieting, and iodide of potassium are about the only means on which reliance can be placed. Various drugs have been recommended, but they are mostly of but little use. Among such may be mentioned digitalis, ergot, and acetate of lead. With regard to the first-mentioned drug it is difficult to see how it can be of any service, as its action is to increase the force of the circulation, which is just what it is desirable to avoid. Opium in grain doses, or morphine subcutaneously (gr. $\frac{1}{4}$ to gr. $\frac{1}{2}$), is to be recommended for the relief of pain, and benefit has occasionally been experienced from the application of an ice-bag over the seat of the aneurysm. The first thing in treating a case of aortic aneurysm is to confine the patient strictly to bed in the recumbent position. The diet should be restricted after the plan recommended by the late Mr. Tuffnell. His scale is as follows:—For breakfast—Bread and butter, 2 ounces; cocoa or milk, 2 ounces. Dinner—Boiled or broiled meat, 3 ounces; potatoes or bread, 3 ounces; light claret, 4 ounces. Supper—Bread and butter, 2 ounces; milk or tea, 2 ounces; the solids thus amounting to 10, and the liquids to 8 ounces. Something more, both of solid and liquid food, may be allowed without jeopardizing the beneficial result to be looked for; and, as

against thirst, a little ice may be allowed occasionally. Two or three months (preferably the latter) would constitute a fair trial of this mode of treatment. The presence of aortic regurgitation is a distinct contra-indication for Tuffnell's method, as in such a case the compensatory hypertrophy of the left ventricle, which it is so desirable to maintain, is likely to fail under the combined influence of the low diet and prolonged rest. As to medicines, the iodide of potassium should be prescribed in doses of 10 grains three or four times a day to begin with, and this may be increased by 5 or 10 grains weekly till 60-grain doses are reached. The drug is supposed to increase the coagulability of the blood, to diminish arterial tension, and to strengthen in some way the wall of the sac. The increase in dose should be stopped (according to Dr. G. W. Balfour) whenever the pulse-rate begins to be permanently increased. If the disagreeable effects comprehended under the name "iodism" be produced, it should be omitted for a day or two, and then resumed; and when the limit of dose, which will vary in different cases, is reached, it should be steadily persevered with for many months.

Whatever effects the drug may produce on the wall of the sac there can be no question of its power to relieve the distressing pain so much complained of; and, as to the length of time during which, and quantity in which, it may be taken, the writer may mention that he has had under his care a woman who took it in considerable doses (grs. xx) three times a day, with very little intermission, for five years, and has another under treatment at the present time who has taken upwards of 60 grains every six hours for several weeks. In both cases the intermission of the drug has been followed by an increase in the symptoms, but in neither is there evidence that coagulation has taken place in the sac.

Surgical treatment seeks to procure coagulation in the sac of an aortic aneurysm by three methods—galvano-puncture, distal ligature, and the introduction of some foreign body, such as steel wire, horsehair, or catgut. None of these has been very successful, and all are dangerous. It is not too much to say that the average duration of life has been shortened rather than lengthened by surgical procedure in aortic aneurysms; and yet there are unquestionably cases on which it is right to make the trial of such treat-

ment. But it should only be done after failure of other methods, in carefully selected cases, and with the intelligent consent of the patient. Galvano-puncture and the distal ligature have in a few cases resulted in cure, at least for a term of years; as to the other method mentioned, very little good has come of it hitherto, but it may be said to be still on its trial. Here again the presence of aortic regurgitation is a contra-indication to all such treatment, as clots, if formed, could hardly fail to be dislodged, and carried onwards in the blood-stream until peripheral vessels were blocked. In the case of some aneurysms of the abdominal aorta—those, namely, which are not too high up in the vessel—besides the methods of treatment already enumerated, there is another plan—viz., the application of pressure above the sac, with a view to interrupt for some hours the passage of blood through it and so to cause clotting. Cures have occasionally resulted, but there is great danger of setting up inflammation of the intestines, and possibly gangrene of the bowel, or of one or both extremities.

DAVID W. FINLAY.

APHASIA.—Under this heading will be considered the disorders of speech usually associated with hemiplegia, but which also occur as a temporary symptom after some right-sided convulsions. They may be classified as (1) aphasia, (2) amnesia, (3) mechanical difficulties of articulation.

1. **Aphasia**, called also motor aphasia and ataxic aphasia, denotes the deprivation of the faculty of articulate speech, and is usually associated with an inability to write (agraphia). The aphasic can usually make some incoherent sounds, thereby showing that the vocal apparatus is not affected, and sometimes can say one or two words, as "Yes" and "No," or he uses some expression, such as "Baba," in reply to every question. He usually understands questions spoken to him, and also written questions; he can point out objects named, although he cannot name them; he knows when they are called by the right name, but he cannot repeat the name of an object when told to do so. The word spoken calls up in the patient's mind the idea of the word, but he is unable to repeat it, as the part of the brain which registers the word and executes the repetition of it is damaged. This area of the brain is in the posterior part of the *left* third frontal convolution of the cor-

tex and in the neighbouring part of the island of Reil, and consequently aphasia is nearly always associated with *right* hemiplegia. In the cases recorded, where it was present with left hemiplegia, the patient was left-handed. The condition of the aphasic varies in different cases; some can neither speak nor write; some can write, but cannot speak—*aphemia* (Bastian); some can speak a little, but cannot write—*agraphia*; or perhaps can only perform the very automatic action of writing their names; they can all understand spoken language, and, usually, written questions. Although aphasics cannot speak or can only use a few words, they will sometimes, when annoyed or bothered, swear or say "Oh dear!" or even answer "No" correctly to a question. That these are only automatic reflex utterances is proved by the fact that they are quite unable to repeat the expression voluntarily when told to do so directly afterwards. Aphasics can laugh, and sometimes sing and play at games, such as draughts, &c.

2. **Amnesia**, or sensory aphasia, is a condition which may exist alone or in association with aphasia, as just described. Three forms of amnesia are met with; they may occur either separately or in combination with each other. In one form of amnesia the patient can articulate quite well, and can converse and answer questions, but every now and again he forgets a word, and either comes to a standstill or puts in wrong words, or his language becomes a meaningless jargon; he knows what he wishes to say, but he cannot find the necessary word owing to a defect in the co-ordination of the speech centres. When asked the name of an object, he will say, "I know," but he has forgotten what it is, or he will make an attempt and produce a word something like the one required; but when the word is spoken he can repeat it correctly. In some cases "nouns" have disappeared from the patient's vocabulary (Broadbent). Two other forms of amnesia are met with, called "word-blindness" and "word-deafness," in which the patient can speak and write fluently. In *word-blindness* all written communications reaching the speech centre through the sense of sight are cut off. He cannot read or understand written language; he may recognize and pronounce the names of letters, but he cannot understand the meaning of the words they form. He can express his thoughts in writing and write from dic-

tation, but he cannot read or understand what he has written; he can also copy drawings and writing, but he usually copies the exact type and does not change printed into written characters. With all this he is able to speak and converse fluently, unless the word-blindness is complicated by motor aphasia. In cases which have been examined after death the lesion has been found to be in the angular gyrus of the left side—the convulsion which has been found by Ferrier to be a fundamental portion of the visual centre. The angular gyrus is in communication by connecting fibres with the adjacent third frontal convolution, and in word-blindness either these fibres are injured or a part of the angular gyrus is damaged. In the other form of amnesia, *word-deafness*, the patient has lost the power of executing commands reaching him through the sense of hearing. He is not deaf to ordinary sounds or to music, but he cannot understand spoken words. He can usually read, write and speak well, but in some cases his speech is a mere senseless jargon, owing to the fact that he is unable to call up the auditory impression or to hear the sound of the word he wishes to utter. This is also the case sometimes in reading aloud: he sees the word correctly, but cannot recall the sound of it so as to pronounce it properly; he speaks fluently, but does not know that he is talking nonsense. Though these patients can usually understand simple written commands, they cannot always comprehend long sentences. This may be due to the fact that, in reading, complicated words require not only to be received by the visual centre, but the sound of them has also to be recognized by the auditory word-centre before they can be understood, and, if the auditory word-centre be damaged, the mere visual recognition is not sufficient. These patients can copy sentences correctly, but they cannot write from dictation. The lesion found in cases of word-deafness is situated in the superior temporo-sphenoidal convolution, especially that of the left side, the part assigned by Ferrier to the auditory centre, and either this centre is damaged or the connecting fibres between this gyrus and the third frontal convolution are destroyed.

3. **Mechanical Difficulties in Articulation.**—This form must be carefully distinguished from aphasia and amnesia. Here there is no difficulty in understanding written or oral communications.

The patient is usually able to speak, but the words are “thick” and the pronunciation is imperfect. In some cases, however, the patient is unable to utter a sound, and this is associated with defective movements of the tongue and difficulty in swallowing. In such cases the lesion is situated in the pons Varolii or medulla. Complete loss of all articulation is also produced by a double hemiplegia, which destroys the fibres in the internal capsules coming from the articulatory centres (third frontal convolution) of both sides. If the fibres in the internal capsule coming from the articulatory centre of one side only, especially the right, be involved, the patient is able to speak, as each centre acts bi-laterally, but his speech is often indistinct. The quality of the speech differs according as the soft palate, the tongue, or the lips are affected.

The *prognosis* in aphasia and amnesia varies very much in different cases. Some patients, especially those advanced in age, never improve, and for the rest of their life can utter only one or two meaningless words, while other cases steadily improve, learning fresh words until they almost completely recover.

The *treatment* of aphasia is the same as that of the hemiplegia which so often accompanies it, but, in addition, very much may be done in teaching the patient fresh words and the sounds of letters. Many patients have to learn speech from the beginning, just like a child. In other cases it is useful to get the patient to learn to spell words by using detached letters. In short, every channel by which he can be made to re-learn the functions of speech which have been lost must be made use of. The theory of the recovery from aphasia is that the opposite hemisphere—in most cases the right third frontal convolution—takes on the work of the damaged left side, and in time, by education, is able to perform the functions of its fellow.

C. E. BEEVOR.

APHONIA.—For the production of voice it is necessary that the vocal cords should first be fixed in the proper position, and that they should then be thrown into vibration by air forced through the glottis by an expiratory effort. Aphonia, or loss of voice, may be due, therefore, to (a) interference with the approximation of the vocal cords, (b) alterations in the cords themselves impeding their vibration, and (c) a

deficiency in strength of the expiratory current.

(a) The non-approximation of the cords may be due either to nervous, muscular, or mechanical causes. To the former class belong conditions producing paralysis of the adductor muscles of the cords, the so-called hysterical aphonia is a member of this group. In certain inflammatory affections, the muscles of the larynx become infiltrated, and are consequently unable to adduct the cords properly, or to render them sufficiently tense. Swelling about the arytenoid cartilages, new growths, &c., may set up changes in the crico-arytenoid joint, and thus lead to mechanical interference with the approximation of the cords. (b) The vocal cords may be destroyed by ulceration, be adherent to the sides of the larynx, or be so altered by the presence of a new growth as to be unable to vibrate properly. (c) Feebleness in the expiratory current may be due to advanced disease of the lungs, to loss of power in the respiratory muscles, or to conditions such as obstruction of the trachea by tumours, tracheotomy and perforating wounds of the trachea, which prevent the air current from impinging upon the cords with sufficient force.

F. DE HAVILLAND HALL.

APHTHÆ.—Much confusion has arisen from the use of this term as a synonym for *thrush*; the latter should be restricted to that form of stomatitis dependent on the presence of a vegetable parasite, the *oidium albicans*.

Symptoms.—Aphthæ, or aphthous stomatitis, commences as whitish, opaque, elevated spots on the tongue, buccal mucous membrane, or pharynx. At their commencement they are vesicular, but the vesicles soon rupture and leave small oval or circular ulcers, covered with a yellowish-grey or whitish slough, and surrounded by an inflamed margin. The patient is usually feverish; the mouth is sore and tender, and there is difficulty in sucking or taking food. Salivation is invariably present; the breath is generally foul, and there is frequently intestinal irritation. The disease has a tendency to come in crops, the patient getting nearly well, and then having a relapse.

Diagnosis.—It is distinguished from thrush by the larger size of the patches, and their irregularity, by their inflamed margin, and by the absence of the characteristic parasite found in the

latter disease. It may be confounded with herpes of the pharynx, but in this comparatively rare affection the vesicles are larger and more distinct. In itself, aphthous stomatitis is not a severe or dangerous affection, more especially in childhood, but coming on in old age or in patients exhausted by disease, it is of an unfavourable augury.

The *pathology* of the disease has been sufficiently indicated in the description of the mode of onset. The only point of difference of opinion is as to the condition which precedes the stage of ulceration. Some authorities maintain that this is of a vesicular nature—this is the view taken by the writer; while others maintain that there is a fibrinous exudation.

Etiology.—The disease is chiefly observed in children between the ages of six months and three years. It is generally associated with some febrile affection, such as measles, or occurs as a concomitant of dentition or intestinal derangement.

Treatment.—At the commencement, unless diarrhœa exist, it is well to give a mild aperient, such as a teaspoonful of castor oil or of fluid magnesia; if diarrhœa be present, 2 or 3 grains of carbonate of bismuth, with an equal quantity of the bicarbonate of sodium in cinnamon water, given every four or six hours, will quiet the bowels; a mixture containing 2 minims of liquor potassæ, 2 of ipecacuan wine, 10 of syrup of tolu in 2 teaspoonfuls of dill-water given every four hours, will generally relieve the gastro-intestinal irritation accompanying aphthæ. The specific, however, for the disease is undoubtedly chlorate of potassium, which may be given in 2 to 5 grain doses, either alone in some sweetened water, or in combination with either of the mixtures just mentioned. Locally, the greatest cleanliness is requisite. If the child be old enough, it may be taught to wash out the mouth every two or three hours with a gargle containing 20 grains of borax and 20 minims of glycerine in the ounce of water. In the case of infants it will be necessary to swab out the mouth with the same solution by means of a piece of soft rag securely attached to a holder. Great attention should be paid to the diet, which should be plain and unstimulating; and, in the case of children using the bottle, the greatest care should be given to ensure that both it and the tube are perfectly sweet.

F. DE HAVILLAND HALL.

APNŒA has been used by some writers as synonymous with asphyxia, but it is now only employed in the sense in which it is used by physiologists—viz., to denote the condition in which the blood is too highly arterialized, *i.e.*, contains too large a proportion of oxygen, and consequently fails to stimulate the respiratory centre in the medulla; the result being that respiration is arrested.

APOPLEXY, Cerebral.—A sudden loss of consciousness, due to changes in the brain, usually the result of (1) hæmorrhage, (2) thrombosis, or (3) embolism. Cases in which no lesion can be discovered after death are described as (4) simple apoplexy.

Symptoms.—There is sudden loss of consciousness, and the patient falls to the ground, but there is no failure of the heart's action as in syncope. Before the attack there may have been tingling and numbness in the limbs, with headache and drowsiness. In the attack the patient lies with all the limbs relaxed, the pupils are dilated and react very slightly or not at all to light, the respiration is stertorous, the face is either flushed or pale, and there is retention of urine or it is passed involuntarily. In some cases the patient is able to swallow, but in others the power of swallowing is lost. The superficial reflexes are often abolished. Death may occur in a few minutes, or consciousness may remain in abeyance for hours or days. Later on there are often signs of paralysis on one side, that opposite to the seat of lesion in the brain, the paralysed limbs being flaccid; the pupils are often unequal, and there may be conjugate deviation of the eyes and rotation of the head *away* from the paralysed side, and *towards* the non-paralysed side—*i.e.*, the patient looks towards the side of the lesion in the brain. The mouth is drawn over to the non-paralysed side. These phenomena are due to the unopposed action of the non-paralysed muscles. Should recovery take place, consciousness gradually returns, when the patient is usually found to be hemiplegic—*i.e.*, he has lost power in one-half of the body (*see* HEMIPLEGIA). There is often slight elevation of temperature on the paralysed side. The state of the body temperature has been shown by Bournville to be very important. In cases in which death occurs in a few hours, the temperature falls to 96° or lower, and goes on sinking; when it occurs in ten to twenty-four hours, the initial fall is followed by a

rapid rise till death ensue; if death is to happen in a few days, there is a stationary period after the fall, and from the second to the fourth day a rapid rise occurs. Recovery is probable when there is an initial fall, followed by a slight rise for three or four days, and a return to the normal. In Bournville's observations, the temperature was taken in the rectum.

The degree of unconsciousness, and the severity of the attack, depend upon the position and the extent of the lesion. The loss of consciousness is due to shock produced by the effused blood ploughing up and lacerating the brain substance, or to anæmia, owing to the blocking of the vessels supplying a part of the brain. It is greater when it is caused, as in the former case, by hæmorrhage, than in the latter, when it is due to thrombosis or extensive embolism.

1. **Hæmorrhage** may occur either into the meninges or the substance of the brain, pons, or medulla; in the latter case it is often due to rupture of an aneurysm, about the size of a small pea, of the middle cerebral artery, especially the left; or of the basilar or other artery of the brain: or to rupture of miliary aneurysms the size of $\frac{1}{25}$ th of an inch or less, which are sometimes found in large numbers on the arteries about the optic thalamus and in other places. Syphilis, alcoholism and Bright's disease are the most frequent predisposing causes; in the latter disease the arteries are degenerated, and the increased blood pressure brings about rupture. Softened patches in atheromatous vessels may give way, and so cause hæmorrhage.

2. **Thrombosis** results from narrowing of the arteries; the change may be either local or general. Nodules are produced between the inner coat and the elastic laminæ; these project into, and narrow the lumen of, the vessel, or produce a rough surface on its interior, conditions which favour the formation of thrombi. A special form of disease of the cerebral vessels is caused by syphilis. Atheroma, either localized or diffuse, is frequently present in the subjects of chronic Bright's disease. Wasting diseases also, such as phthisis and carcinoma, by slowing the blood-current, predispose to thrombosis. The arteries most affected are the middle cerebral, basilar, and carotid.

Thrombosis of the superior longitudinal sinus sometimes occurs in anæmic girls, and clotting in the lateral sinus is frequently found in association with caries

of the petrous bone. Meningitis and erysipelas of the face and scalp may also present this complication.

3. **Embolism.**—Although embolism of the cerebral vessels frequently occurs without causing loss of consciousness, still if the emboli be numerous or the vessel occluded a large one, the ensuing anæmia of the part supplied will be severe enough to cause unconsciousness. Anæmia and, subsequently, softening of the part supplied by the blocked vessel ensue, owing to the absence of any collateral circulation above the circle of Willis. The left middle cerebral and internal carotid are the arteries most often affected, owing to the fact that the orifice of the left common carotid lies more directly in the course of the blood-current than does that of the innominate.

4. **Simple apoplexy** is the term applied to cases of death from coma, when no lesion is found in the brain. It is probable that many of these are cases of epileptic coma (Gowers).

Ingravescent apoplexy is a name given to loss of consciousness with slow onset. In such cases there is usually a gradual leakage of blood from the ruptured vessel.

The *diagnosis* of apoplexy from other forms of unconsciousness is considered under DISORDERS OF CONSCIOUSNESS. Of the different forms of apoplexy, it may be said that in hæmorrhage the unconscious state is always longer and more profound than in that due to thrombosis or extensive embolism. Hæmorrhage and thrombosis usually occur in old people, and embolism in younger persons. Prodromata such as headache, tingling, numbness, and drowsiness are present in the two former and not in the last.

The *prognosis* of apoplexy depends on the cause, being much more serious in hæmorrhage. Death may ensue while the patient is unconscious. Profound coma with complete relaxation of the limbs, involuntary micturition and abolition of all the superficial reflexes, are very serious symptoms, and probably indicate the presence of extensive hæmorrhage into the ventricles, the meninges, pons or medulla. Any increase in the symptoms is usually due to a further hæmorrhage, and is of bad omen, whilst a speedy return of consciousness indicates a favourable issue of the attack. The state of the temperature is a valuable guide in prognosis.

Treatment.—In apoplexy absolute rest

is essential; the head should be raised a little, and the clothing round the neck loosened. Warmth may be applied to the extremities, and sinapisms to the calves of the legs are considered to have some effect in lessening the amount of blood in the brain. If there be signs of cyanosis and laboured stertorous breathing, with a tense incompressible pulse, venesection is recommended by some writers, but is rarely of much service, and is a mode of treatment now seldom adopted. The bowels should be opened by a drop of croton oil placed upon the tongue. In hæmorrhage stimulants are, as a rule, to be avoided, but if the pulse become very feeble they may be required, but should be administered with extreme caution. When the diagnosis of thrombosis or embolism can be made, ether and ammonia or alcohol should be given if the pulse show any signs of failure, and when this is associated with cold extremities and tendency to collapse purgatives are contra-indicated. The catheter should be passed if there be retention of urine. If the patient be unable to swallow, and the state of unconsciousness be much prolonged, nutrient enemata may be required.

C. E. BEEVOR.

ARCUS SENILIS is the greyish white opaque ring so often seen near the margin of the cornea. As a rule, it commences at the upper part of the cornea and then attacks the lower, two crescent-shaped bands resulting, which gradually coalesce to form a complete ring. There is always a narrow rim of healthy cornea left outside it. The colour at first is greyish white, and gradually becomes more opaque as age advances. An arcus is not often seen before the age of forty, and is very rarely absent in old age. When met with in comparatively young people, it is by some regarded as an indication of a tendency to fatty degeneration of other parts of the body, especially of the heart and arteries. But the connection between arcus senilis and fatty heart is extremely dubious. The appearance is due to a fatty degeneration of the cornea, and is almost invariably symmetrical, though occasionally more marked in an eye which is the subject of long-standing disease. It is not a condition calling for treatment.

ARSENIC, Poisoning by.—Metallic arsenic is not poisonous, but arsenious acid or white arsenic is highly so. It is a white crystalline or powdery substance

very insoluble in water, and is therefore usually administered in the solid form in cocoa, arrowroot, gruel, &c.; the addition of an alkali or an alkaline carbonate increases its solubility.

Acute Poisoning.—The *symptoms* generally appear after an interval, which may be half an hour or an hour, and consist of a burning pain in the mouth extending to the stomach, nausea, vomiting, great thirst, and hoarseness; the abdomen is tender and may be swollen; the vomited matters may be white or black, if the powder had been mixed with soot; or blue, yellow, or green, if mixed with indigo. Diarrhœa and tenesmus are usually present, with burning pain in the intestines and excoriation of the anus. Difficulty of breathing and frequent painful micturition are sometimes complained of. Death may occur within twenty-four hours, or the symptoms may be less severe and there may be remissions. In this variety nervous symptoms, such as cramps, tremors, or even general convulsions, are sometimes met with. In other cases, the irritant symptoms are almost wholly in abeyance, faintness being the chief or only symptom. In cases that do not prove fatal, local paralysis in one or more of the limbs may persist after recovery from the gastric and abdominal affection. The above constitute the symptoms when the poison has been given in one large dose, but it is frequently administered in small and repeated doses. The chief symptoms then will be severe, and continued ill-health for which no cause can be assigned, a liability to vomiting, especially after each meal, or after a particular meal each day, and marked emaciation. Numbness, tingling in the limbs, conjunctivitis, intolerance of light, eczema, and falling off of the hair, are amongst the minor symptoms in such cases; the patients are irritable and depressed, and sometimes suffer from a general paralysis, closely resembling that due to alcohol; when a complete change of the surroundings is effected, the symptoms disappear.

Post-mortem Appearances.—The mucous membrane of the stomach is almost always deeply congested and ecchymosed, rarely ulcerated; it may be smeared with a thick white or yellow paste, the colour being due to the formation of a sulphide of arsenic. The duodenum, and sometimes the whole alimentary track, is usually inflamed; the rectum seldom escapes. The mucous membrane of the mouth and œsophagus will be found in-

flamed and whitened. Should the patient have survived some days, fatty changes will be found in the liver and kidneys, and the spleen will be enlarged and soft. The blood is fluid. Arsenic prevents decomposition, and, in bodies that have been buried for some time, it will often be quite possible to make out most of the above signs in cases of arsenical poisoning.

Treatment.—The stomach-pump can only be used when the patient is seen within a very short time of swallowing the poison; vomiting should be encouraged, and milk and albuminous drinks, such as white of egg, barley water, linseed tea, may be administered by the mouth. When the poison has been given in solution, and the patient is seen early, some freshly prepared ferric hydrate may be given as an antidote. This is made by precipitating tincture of perchloride of iron by carbonate of sodium and filtering. It should be given in hot water and in large quantities, or dialysed iron in doses of one ounce may be given repeatedly. By these means an insoluble ferric arseniate is formed. Diluents should be given freely, and if there be much prostration stimulants will be required.

Chronic Poisoning.—There are other preparations of arsenic which may be dangerous; of these, the most important is the aceto-arsenite of copper or emerald green, which at one time was largely used in the manufacture of wall-papers and artificial flowers. An arsenical wall-paper is usually, but not necessarily, green. The danger from such a paper is diminished by varnishing and glazing. Those who suffer most are the paper-makers, the paperhangers, and the people who inhabit the rooms so papered. The symptoms are those of general indisposition, coming on very gradually, but steadily progressing; headache, nausea, and languor being succeeded by coryza, cramps, pain and tenderness in the abdomen, and a marked degree of cachexia. Paperhangers are liable to eczema about the root of the nostrils, the backs of the ears, bends of the elbows, insides of the thighs and scrotum. Removal of the exciting cause is sufficient to effect a speedy cure.

ARTERIES, DISEASES OF.—

Most of the diseases affecting arteries may be comprehended in two classes, according as they depend upon inflammation or degeneration.

I. Inflammatory Diseases of Arteries.—**ACUTE ARTERITIS** occurs only

locally. It is due to several causes, such as the presence of an embolus; or, in the case of the aorta, to the friction of a ruptured valve or a long tag-like vegetation. In such cases ulceration may ensue, although perforation of a vessel is exceedingly rare. But there is another class of cases in which the destructive influence comes from the outside (*e.g.*, cancerous ulceration), and perforation from this cause occurs with tolerable frequency.

ACUTE ENDARTERITIS is seldom seen except in very large arteries, being most frequent in the aorta. The internal coat of the vessel is found to be swollen, and elevated into small semi-transparent gelatinous patches of circular or irregular shape which are soft and elastic, but rarely show ulceration. They consist mainly of embryonic cell growth. All the coats are ultimately affected.

PERIARTERITIS.—The inflammatory change just mentioned, which is at first limited to the internal, may by extension outwards affect the external coat of the artery, the middle coat either escaping altogether or showing comparatively but little evidence of disease. The tissue of the external coat is thickened, and the fasciculi of connective tissue are separated by groups of embryonic cells. In the case of small arteries, however, periarteritis is the result, not of change within, but from outside the vessel.

CHRONIC ENDARTERITIS (also named *Atheroma*, and *Arteritis Deformans*) is very commonly met with. It is especially a change of advancing age, and is partly degenerative. It is typically seen in the aorta, although frequent also in some of the smaller arteries (*e.g.*, those of the brain). It may be preceded by fatty degeneration, with which, indeed, it is sometimes confounded. Its immediate cause is mechanical irritation due to the force of the circulation.

Etiology.—It is still a moot point how far syphilis may be concerned in the production of this form of disease. Age, as already stated, is an important factor in its causation, and the male sex is more obnoxious to it than the female, owing mainly to the fact that the bulk of hard manual labour falls on the former.

Morbid Anatomy.—Taking the arch of the aorta as the type, the internal coat of the vessel is seen to be thickened in patches which are of a dull yellowish white colour, hard and opaque, causing considerable irregularities and encroaching on its lumen. The vessel itself is rendered rigid and inelastic. Microscopically, the thickened internal coat

consists of dense connective tissue infiltrated with numerous round cells. In the more advanced patches fatty degeneration is also found, which is brought about by disintegration, first of the cells and then of the intercellular material. As a result, cavities may be formed containing molecular debris and cholesteroline: this constitutes the so-called “*atheromatous abscess*.” If the endothelium covering one of these patches be destroyed and the abscess exposed, an “*atheromatous ulcer*” is formed. It should be mentioned, however, that these names are used only for convenience, both being, pathologically speaking, incorrect.

The results of chronic endarteritis may be very serious. *Atheromatous* patches become calcified, and, acting as foreign bodies, fibrinous deposits form upon them; these may gradually increase until the channel of the vessel is completely obliterated (*see THROMBOSIS*), or they may be washed off by the blood-stream and carried to smaller vessels, which they block (*see EMBOLISM*), the consequence in either case being that the blood supply beyond the point of blocking is cut off unless the circulation can be carried on by collateral channels, and death of the part may take place. Fatty degeneration is another result affecting in a very marked way the cerebral arteries, being here a fruitful cause of cerebral hæmorrhage. The occurrence of aneurysm also is favoured by the weakening of the wall of the vessel and the loss of its elasticity (*see ANEURYSM*).

Diagnosis.—Except in the case of arteries which may be felt, the diagnosis can only be a matter of inference. If arteries which are accessible to the finger be rigid and tortuous, we may with reason suspect that the same condition is present in those which are beyond our reach, especially when the investigation is called for by conditions which are led up to by arterial disease (*e.g.*, cerebral embolism or thrombosis, or gangrene of a limb).

Treatment.—This can only be prophylactic and palliative, and must consist in moderation in everything, especially in food and drink, and in abstinence from over-exertion of any kind, so that the circulation may be kept as quiet and regular as possible.

Prognosis.—The disease being progressive, the ultimate prognosis is grave, but evil results may be postponed for years by care and judicious management. Any symptom indicating implication of the cerebral arteries makes the outlook so much the worse.

ENDARTERITIS OBLITERANS.—Inflammation of the interior of an artery may progress to such an extent as to bring about a complete closure of its lumen. To this the name endarteritis obliterans, or obliterative arteritis, has been given. It occurs in the smaller arteries, notably those of the brain, and is usually due to syphilis. The inner coat of the vessel is the primary seat of the disease, although the outer coat is also sometimes affected and becomes marked by nodular thickenings. The thickenings tend to become vascularized, and do not break down as in atheroma. The effect of this condition is to cut off the blood-supply, leading, in the case of the brain, to softening and paralysis. As regards treatment, much may be accomplished by the use of the ordinary anti-syphilitic remedies, particularly mercury.

ARTERIO-CAPILLARY FIBROSIS.—This is the name given by Gull and Sutton to the change found in the small vessels in the subjects of granular contracted kidney. The outer and inner coats of the vessels are, according to these observers, thickened by a hyaline-fibroid formation, and this not only in the renal vessels, but generally throughout the body. The result is diminution in the calibre of the vessels, obstruction to the circulation, and consequent hypertrophy of the left ventricle (*see* BRIGHT'S DISEASE).

II. Degenerative Diseases of Arteries.—**FATTY DEGENERATION**, apart from atheroma, is sometimes found to affect the internal coat. It is seen typically in the aorta, and may be found in quite young subjects, presenting the appearance of yellowish, opaque streaks and spots scarcely elevated above the surface. On microscopic examination of a patch, it is seen to consist of the cells of the internal coat in a state of fatty change.

CALCIFICATION is one of the results of atheroma. It also occurs as a primary change, in which case it is the middle coat of the vessels which is most frequently affected. Although it is found occasionally in the aorta and other large vessels, it selects preferentially those of smaller size. The muscular fibre cells become infiltrated with lime salts, and the result appears in hardness and rigidity of the arterial walls. This change is frequently present in cases of senile gangrene.

ALBUMINOID DEGENERATION is found in the small vessels of those organs which are affected by that disease, notably the

liver, spleen, kidneys, lymphatic glands, and intestine. It is a common result of long-continued suppuration and of syphilis.

Raynaud's Disease (*q.v.*) may be mentioned, in conclusion, as another variety of disease of arteries which does not come under either of the classes already described.

DAVID W. FINLAY.

ASCITES (Dropsy of the Peritoneum).—Ascites may be part of a general dropsy, the result of disease of the heart or kidneys, or it may be of local origin. In cardiac disease it depends upon the failure of the pumping action of the heart, by which the peritoneum—a large lymph space—is kept dry; in renal disease it results from more complex and obscure causes, in which the following factors co-operate:—(1) Accumulation of water in the blood from failure of the kidneys to secrete sufficient urine; (2) increased outflow of watery lymph from the capillaries, partly from the altered state of the blood, partly owing to increased permeability of the vessels, the consequence of an alteration in their walls. Cohnheim and Lichtheim, in their experiments on the production of dropsy by artificially rendering the blood more watery, found that dropsy of the peritoneum invariably followed.

Ascites of local origin results from (*a*) an obstruction to the portal circulation, or (*b*) some affection of the peritoneum itself—*e.g.*, chronic inflammation, tubercle, or malignant disease. Obstruction to the portal circulation is the most common cause, and is generally due to atrophic cirrhosis of the liver (*q.v.*). In some cases of cirrhosis, owing to the development of a collateral venous circulation, no dropsy ensues, but this is exceptional.

In rare instances ascites is caused by blocking of the portal vein from thrombosis or from the presence of an enlarged gland in the hilum of the liver.

Chronic inflammation, tubercle, and cancer cause effusion of fluid by blocking the lymph paths by which it is normally removed from the cavity, whilst at the same time there is an increased outflow from the capillaries.

In simple dropsy the fluid in the peritoneal cavity is clear yellow serum, which coagulates on standing. It usually contains more water and less albumen than the fluid in the pleura and pericardium, but less of the former and more of the latter than that in the subcutaneous

tissues. In renal dropsy it often contains urea. In inflammation, tubercle, and malignant disease the fluid is turbid, highly albuminous, sometimes quite viscid, and contains shreds of lymph, fragments of new growth, and may be tinged with blood. In simple dropsy the peritoneum is opaque-looking from œdema of its endothelium. In chronic inflammation it is swollen, softened, and covered with lymph, and in tubercle and malignant disease it is studded with these growths. Chronic inflammation may originate from changes in some abdominal or pelvic organ, inflammation of the uterine appendages being a common cause. In cases of ascites of long standing, the result of portal obstruction, the peritoneum, including its reflexion over the liver, is often found covered with a thin, white membrane, which can be peeled off from its surface, and, which when held to the light, is seen to possess a finely fibrous texture. The portion removed from the surface of the liver—*e.g.*, in a case of atrophic cirrhosis—may be fenestrated, the apertures corresponding to the nodules. By some this condition is regarded as primarily a peri-hepatitis, but more probably it is the result of a slight chronic peritonitis caused by the presence of the fluid, as a precisely similar condition of the pleura is seen in long-standing hydrothorax. Tubercle may be primary, or secondary to tubercle elsewhere; it is especially frequent in connection with tubercular ulceration of the intestine. Malignant disease of the peritoneum is most often secondary to cancer of the stomach, intestine, liver, or ovary, or to sarcoma of the pleura. Cancer of the peritoneum when primary is usually of the colloid variety.

Signs.—If the quantity of fluid be considerable, the abdomen becomes uniformly swollen. When the patient lies on his back, the fluid gravitates to the flanks, so that there is a convex curve from the costal border to the iliac crest, and on percussion the note in the flanks is dull, whilst in the umbilical region it is clear. On turning the patient on to his side, these phenomena are reversed, a clear note being elicited in the flank which is uppermost, whilst the area of dulness on the lower side rises into the umbilical region. When the walls of the abdomen are tense, a *percussion wave*, usually termed “*fluctuation*” (*q.v.*), may be felt by laying one hand lightly on one flank, the patient lying on his back, and tapping

with the fingers of the hand on the opposite side.

Treatment.—This must depend upon the nature of the case, and forms part of the treatment of special diseases which are discussed elsewhere. Fluid in the peritoneum is best removed by *paracentesis* (*q.v.*), and the repeated performance of that operation may sometimes lead to a cure of the condition, even though the original cause, *e.g.*, cirrhosis of the liver, remain.

If the amount of effusion be insufficient to justify operation, its removal may sometimes be effected by the administration of purgatives and diuretics. The use of bitartrate of potash electuary is sometimes very successful—*R Potassii bitartratis* ʒss, *mellis* ʒj; sig. a teaspoonful to be taken every two hours till the bowels are freely moved. Or it may be combined with jalap—*R Potassii bitartratis* ʒss, *pulveris jalapæ* grs. x, *mellis* ʒj; sig. a teaspoonful to be taken every two hours till the bowels are freely moved. This treatment can be persevered with daily, but is apt in some cases to cause gastric derangement.

The use of hydragogue cathartics, such as elaterium (gr. $\frac{1}{4}$), gamboge (gr. j), colocynth (gr. j), is not free from danger.

Diuretics are of little use when the ascites is excessive. The venous pressure seems to be too great to allow them to act. In cases of moderate effusion, however, the resin of copaiba in doses of 10 to 15 grains is often of service.

Several cases of tubercular peritonitis with effusion have recently been successfully treated by laparotomy and washing out the peritoneal cavity. A trial of this method should therefore be made in suitable cases.

ROBERT SAUNDBY.

ASPHYXIA includes all conditions which interfere with the function of respiration and prevent the due oxygenation of the blood, death, when it occurs, resulting from poisoning by carbonic acid. Asphyxia is the cause of death in most cases of drowning, in strangulation, suffocation, laryngeal obstruction (whether from foreign bodies, new growths, past ulceration, false membrane, œdema, or spasm), acute capillary bronchitis, paralysis of the chest walls or diaphragm (whether from acute or chronic myelitis, or as a sequel of diphtheria), and in mechanical compression of the chest, and also in certain cerebral states, *e.g.*, epilepsy. Death is sudden when the obstruction to

respiration is at once complete; when incomplete, it is gradual in its onset. The chief feature in all cases of asphyxia is the lividity, which before death always becomes extreme, being most marked in the lips and tongue, which may become almost black. The eye-balls are prominent, the superficial veins stand out prominently, and the breathing becomes more and more embarrassed and shallow. Convulsive twitchings about the mouth and of the limbs are often noticed. The pulse becomes feeble and frequent, but the heart goes on beating after all signs of respiration have ceased.

The *post-mortem appearances* are: Intense venous congestion throughout the body, the right side of the heart and venous system being engorged with black fluid blood, the left side of the heart and arteries being frequently empty. The lining membrane of the air passages will be found intensely congested, and the dependent parts of the body will show post-mortem staining.

The *treatment* would consist of tracheotomy when the obstruction was in the larynx or above it, and artificial respiration, an account of which will be found under the head of DROWNING.

ASTEATOSIS CUTIS is a condition of diminished sebaceous secretion as the result of which the skin becomes dry, scaly, and often fissured. It accompanies prurigo, lichen ruber, and other diseases, in which the sweat secretion is usually proportionally diminished, and occasionally occurs as an independent disease, resulting from frequent washing in hard water, or from the use of certain chemicals (laundresses, photographers). The inunction of lanolin or vaselin gives relief.

ASTHENIA is a synonym for debility, a want of strength. It is a relic of an antiquated pathology, which classified all acute diseases into sthenic, or those which required antiphlogistic remedies, and asthenic, or those which did not call for such active treatment.

ASTHMA.—Asthma may be considered as a disease, and as a symptom of many different diseased conditions. An asthmatic paroxysm consists of a more or less sudden difficulty of breathing, accompanied by a wheezing noise. The affection may be a pure neurosis, a symptom of bronchitis, of some cardiac or renal affection, or due to direct

mechanical irritation of the vagus or its branches. The onset may be sudden. Salter states that he has seen a severe attack developed in thirty seconds, but more often there are some premonitory symptoms, not constant for every case, but known by experience to the patient. These are chiefly, unusual buoyancy of spirits and mental excitement, or depression and a feeling of chilliness, a sensation of irritation in the air passages, vague pains, an itching under the chin, headache, an irresistible sleepiness, flatulent distension of the stomach, and a tendency to pass large quantities of very light-coloured urine of low specific gravity. If the attack take place during sleep, the latter becomes disturbed, and the patient wakes with a fit strong upon him. The afternoon, after an early dinner, is a favourite time for an attack. A slight sense of constriction of the chest, a short dry cough, and a slight wheezing accompanying inspiration are the earliest symptoms; the chest girth is increased, necessitating the loosening of the clothes, and an alteration takes place in the carriage of the body, the shoulders being raised higher than usual.

When an attack is fully developed, the sense of suffocation is terrible. The patient sits up in bed with the elbows fixed and the shoulders raised; sometimes he leans forward with the hands supporting the head, or with the head thrown back resting on the pile of pillows he is obliged to have at his back; or he stands, perhaps near an open window with little clothing on but regardless of cold, the elbows resting on some high piece of furniture. Generally the paroxysms are too severe to permit of the slightest exertion; the perspiration pours off the face from the violence of the respiratory efforts, and at the same time the extremities are icy cold. The countenance is anxious and haggard, and generally pale; there is turgescence of the cervical veins, and sometimes pulsation in the jugulars. Speech is almost impossible. There is no rise of temperature during the attack. The pulse is generally small and quick, but is sometimes intermittent, the intermissions taking place at each effort to inspire. The diaphragm is lowered to its maximum, and there is epigastric pulsation. The chest assumes a barrel shape, and is fixed in the position of deep inspiration. The lungs are full of air, but the air cannot be renewed; the chest feels as if bound with iron, and that relief would follow if it could only be cut open. The efforts of

the patient to introduce air exaggerate the condition still more; all the auxiliary muscles which are strangers to ordinary respiration are called into action, but little movement of the chest results. The respirations do not exceed the normal, but expiration is slow and prolonged. During the height of an attack, the wheezing may be either expiratory or inspiratory. The sound is produced in the larynx, the glottic orifice being spasmodically constricted at an early stage of the seizure.

At some places the respiratory sounds are absent; at others a weak vesicular murmur is heard; but these characters change, sounds becoming audible where previously they were absent, and *vice versa*. This paucity of intra-thoracic sounds is to be accounted for by the diminished amount of the tidal air. The wheezing sounds produced in the larynx and glottis are heard over every part of the chest, and vary with the amount of mucus in the larynx or tubes. The quantity of secretion is very small, and does not much affect the sounds. At the acme of the attack, the walls of the air vesicles are so tense that nearly all the blood is squeezed out of the vessels, but as the distension diminishes, more blood finds its way into the capillaries; secretion takes place, râles of a moist character are developed, and expectoration is sooner or later established. This consists of tough, semi-transparent pellets of mucus of a pale-grey colour, resembling boiled tapioca. This character of the expectoration is peculiar to asthma.

To percussion the chest is hyper-resonant throughout, owing to temporary emphysema, which is present in all cases. The supra-clavicular regions are drawn in, the skin appearing quite tense over the extraordinary muscles of respiration, which stand out like thick cords, and the inter-costal spaces are also made more apparent. The diaphragm is in a state of tonic spasm, its lowered position in some cases causing enlargement of the abdomen; but retraction is the rule. As exhaustion comes on, the severity of the attack begins to abate, respiration becomes more free, and cyanosis decreases. The mucous pellets above described continue to be coughed up for a day or two after the attack, of which they are the result and not the cause.

The *duration of the attack* is often only from two to six hours, followed by sleep, the patient waking up in perfect health, or suffering for a day or two from wheezing and dyspnoea on the slightest

exertion. But sometimes the attacks have a cumulative character, and continue for four or five nights. The duration of the intervals varies, but there is perfect organic integrity of the respiratory and cardiac functions so long as the asthma remains uncomplicated—a proof of the nervous character of the disorder. The attacks are often most severe in the young, and become less marked as the patient grows older. Unless asthma be banished, habitual catarrh and emphysema are established and the respiration is no longer free between the attacks. There is permanent emphysema in inveterate cases, and the ordinary complications and consequences follow—viz., chronic bronchitis, dilated right heart, tricuspid incompetency, and dropsy. As these organic changes take place, the peculiar characters of the asthmatic seizure may be gradually effaced. Spasmodic asthma sometimes subsides if the patient develop bronchitis, but, as a rule, the attacks accompany severe chronic bronchitis.

Of the *pathological anatomy* of asthma there is very little to be said, the disease being of a purely nervous character. In uncomplicated cases nothing abnormal is found after death. In some very rare cases the vagus or phrenic nerve has been found altered by the pressure of tumours. Autopsies on long-standing cases disclose the consequences of asthma—viz., emphysema, bronchial catarrh, bronchiectasis, and lesions of the heart and aorta. Death during a fit of pure asthma is almost unknown; the act of dying, so to speak, relieves the spasm, and the attack subsides. Asthma is rarely recovered from, but the progress is always slow, and without any marked influence upon the duration of life.

Pathology.—As far back as 1720 Floyer entertained the theory that asthma was due to a contracted condition of the bronchia. This theory, that asthma results from a spasmodic contraction of the muscular coat of the smaller bronchial tubes, has been supported by many writers of eminence, whilst others consider that a spasmodic contraction of the diaphragm is the chief cause. A third theory is that the attacks are due to a congested condition of the bronchial mucous membrane analogous to urticaria of the skin, and a fourth that they result from a contraction of the blood-vessels of the lungs analogous to what takes place in the cerebral vessels previous to an epileptic fit. Again, another theory, to which the writer is disposed to give his support, is

that asthma is due to a reflex spasm of all the inspiratory muscles arrested in the act of deepest inspiration, with overdistension of the bronchial tubes and air cells.

Etiology.—All writers agree that asthma is a nervous disease, and that the nervous irritation may be central or peripheral. In those subject to asthma there exists an abnormal excitability of the pneumogastric nerves. When this is increased, a very slight cause is sufficient to bring on an attack; at other times it requires some definite and usually easily recognized cause to produce an attack. This sensitive condition of the pneumogastric nerves is above all things dependent upon locality and digestion. In many cases the disposition is hereditary, and often occurs in gouty families. The disease is commoner in the male than in the female. The effects of locality have been supposed to be due to moisture, the production of ozone, or to atmospheric electricity. It is a fact that many true asthmatic patients are better in a fog, and, above all, in a London fog, which generally causes urgent dyspnoea in those who suffer primarily from bronchitis and emphysema. And it is known that fogs are associated with a strong electro-positive condition of the atmosphere. Certain winds, especially an east wind, act as an exciting cause in some patients. There are many instances of attacks being brought on by electricity.

Indigestion is a fruitful exciting cause; some articles of diet in particular are more obnoxious than others, such as wine, beer, pastry, sweets, and honey. It is a very dangerous thing for asthmatics to go to sleep after a meal before digestion is accomplished; and cold feet independently of anything else, are said to bring on attacks. Patients suffering from cardiac disease often have well-marked attacks of asthma.

Many vegetable emanations, as from hay, privet, and ipecacuanha, produce attacks in persons predisposed to them; also the smell of certain animals, as dogs, cats, rabbits, guinea-pigs, goats, a sweating horse, or a menagerie. Dust of all sorts may also become an exciting cause, and the dust from blankets is particularly objectionable. Immoderate fits of laughter have often been known to produce a paroxysm. Certain conditions of the mind have also a great effect both in producing attacks of asthma and in causing their sudden relief, such as anxiety, grief, or sudden joy. Often, if the mind can be influenced by some cir-

cumstance calculated to produce pleasure and entirely divert the attention, an attack of asthma will pass off. Severe mental strain, as well as absence of employment calculated to interest and excite the mind, are fruitful causes of the continuance and return of many nervous diseases, and among them spasmodic asthma.

Treatment.—The effects of remedies in asthma are very capricious. During a paroxysm emetics are often very serviceable. Relief is experienced when the first sense of nausea and faintness is induced and before the stomach is emptied. Lobelia also relieves attacks directly its depressing effect is produced. Sedatives and antispasmodics are the most serviceable drugs, and many of them have been used with beneficial results; above all in value is the hypodermic injection of morphia. The objection to it is that, if often used, the dose must be increased; but it is better to increase the dose of morphia than to allow the patient to suffer the agonies of asthma. One-sixth of a grain is at first usually sufficient to subdue the symptoms. Tobacco often gives relief when an attack is threatening, but this drug, in common with others that are directed to be used by smoking, is only available when the attack is not very acute, for, when severe, patients have not breath enough to enable them to smoke. *Datura stramonium* and *datura tatula* are both efficacious drugs in some cases, but stramonium sometimes produces intolerable headache. Many proprietary powders, when burnt near the patient and the fumes inhaled, give great relief. The chief of these are Himrod's Powder, Popham's Specific for Asthma, Senier's Asthma Remedy, and Girdwood's Asthma Remedy. Nearly all of them contain some plant of the order Solanaceæ and nitrate of potash. A powder of the following composition is often of great service:—*Pulv. stramonii* ʒj, *pulv. seminum anisi* ʒss, *potassii nitratis* ʒss, *tabaci contriti* grs. xxx, a teaspoonful to be burnt and the smoke inhaled. Nitre-paper alone is a most valuable remedy and useful in the great majority of cases. It is made by saturating blotting-paper in a solution of nitrate of potash (grs. xxx ad ʒj). Chlorate of potash is added to some papers, but the addition is not an advantage, as the paper then burns too quickly and the fumes become suffocating. Some asthmatic patients dare not go to bed without first filling their chamber with nitre fumes; they then sleep in safety. Nitrite of amyl

gives temporary relief, but the effect often only lasts for about ten minutes; the dyspnoea then gradually returns. Iodide of ethyl is also reported to have been useful in some cases; in others it aggravated the attack. Chloroform never fails to subdue a paroxysm, but its effects are as evanescent as the drug. Ether, in the form of Hoffman's Anodyne, often gives partial relief, and chlorodyne is often found useful. Hydrate of chloral has been tried, but with contradictory results. Stimulants are sometimes of value, but usually asthmatics do not bear alcohol well in any form. Coffee is a very old remedy, but, if not taken on an empty stomach, it may impede digestion, and do harm rather than good. Citrate of caffeine has recently been found efficacious in doses of from 1 to 5 grains. The condensed air-bath has been known to relieve an asthmatic attack in patients suffering also from chronic bronchitis and emphysema, but in cases of pure spasmodic asthma it has produced a most dreadful sense of suffocation. A rarefied air is sometimes beneficial, but old asthmatics should avoid high altitudes. Electricity is occasionally successful, but sometimes produces attacks in those predisposed to them if used when the patient is in health and breathing freely. It has not yet been decided what form of electricity gives the best results. Iodide of potassium is one of the most valuable drugs in the treatment of asthma; it should be given in considerable doses—grs. x, or more.

Between the paroxysms the general health should be improved, and the tendency to spasm may be diminished by the prolonged administration of small doses of liq. strychninæ, nux vomica, and arsenic. Belladonna, cannabis indica, bromide and iodide of potassium have also been tried, but with varying results. Of course, if the asthma be complicated by bronchitis, treatment must be directed to the relief of that condition. When warning phenomena are experienced, an attack may often be avoided by calming the excitability of the vagus by fumigation with nitre-paper, or by smoking tobacco or stramonium. If the patient be robust and suffer from abdominal plethora, a brisk purgative will often suffice, followed by light diet and repose for two or three days. At the commencement of an attack, the patient should be raised, or placed in an arm-chair; if in bed, he should be supported comfortably by pillows, the room warmed, the clothes loosened, and all

his wants anticipated. Cutaneous irritation, such as rubbing, the application of a mustard and linseed-meal poultice to the chest, or simply brushing the hair for a considerable time, is often soothing.

For the avoidance of attacks the most potent influences are locality and diet. As regards locality, each patient must seek out for himself a place that suits him, and the sites vary within very narrow limits; but, when once a suitable locality has been discovered, the effect is permanent so long as the patient remains there. There is nothing haphazard or irregular about this influence of locality; a patient knows that in a certain place he will be well, and that in another place he will have an attack; and if repeated twenty times it is always with the same result. This effect of locality is immediate, and peculiar for each individual sufferer. Careful dieting is necessary for all patients, and especially for those with a gouty diathesis. Dietetic treatment involves the avoidance of all indigestible food, of heavy meals, and late suppers, and particularly of those things which experience has proved to be provocative of attacks.

W. E. STEAVENSON.

ASTRINGENTS are substances which produce contraction of the tissues. Internally, they are used to control hæmorrhage or to check diarrhoea, and act in two ways. The so-called constringents coagulate the albuminous tissues in the mucosa, and thus interfere with the circulation and diminish the amount of exudation through the walls of the vessels; of this class are tannic and gallic acids, the persalts of iron, alum, catechu, kino, krameria, and cinnamon. The dilute mineral acids, acetate of lead and nitrate of silver, on the other hand, cause contraction of the vessels, and so arrest hæmorrhage or diminish exudation. Locally, astringents are used to reduce the exuberant granulations of ulcers or are applied to chronically inflamed mucous membranes to diminish secretion. Nitrate of silver, sulphate of copper, and alum are the chief local astringents; they are used in the solid or liquid form, or as a spray.

ASYSTOLISM is a word much used by Beau and other French writers to express an inability on the part of the right ventricle of the heart to empty itself of its contents, a condition met with especially in the later stages of

mitral incompetence. The term has not come into general use.

ATELECTASIS AND COLLAPSE of the Lungs.—The former term implies the absence of expansion of the lungs at birth—*i.e.*, the retention of the foetal condition; whilst the latter implies that lung tissue, previously expanded, has become airless.

Collapse may be brought about by mechanical hindrance to the entrance of air to the whole or any part of either lung, or by the absence of inspiratory traction. In children complete collapse of a whole lobe is sometimes found, the lung tissue appearing perfectly airless. This condition is of purely mechanical origin, although formerly supposed to be the result of inflammation, and described as lobular pneumonia.

The commonest forms of mechanical hindrance to the entry of air are—

(a) Obstruction of the upper air passages by a solid body, or by mucus as in bronchitis; pressure from without, as by aneurysm, enlarged glands, or any form of tumour; spasm of the circular muscular fibres within the walls of the finer tubes.

(b) Pressure exercised upon the lung by solid, fluid, or gaseous accumulations in the pleural cavity. The condition of the lung in cases of pleural effusion is a result of collapse combined with œdema, and is generally termed “carnification.”

To the absence of inspiratory traction must be ascribed the collapse of the margins and of portions of the lower lobes of the lungs, which often occurs independently of bronchial obstruction. The effect of weakness of the chest walls, or of their muscular coverings, as a contributing cause in the production of atelectasis, is seen in the frequent occurrence of the condition in rickety children. The smaller tubes being most subject to obstruction from the inspiration of sticky mucus, it follows that collapse of small tracts occurs most frequently at the surface of the lung. Finally, the gases of the residual air are absorbed by the capillaries of the part, and the vesicles collapse from the natural elasticity of their walls. The collapse of larger tracts, sometimes of a whole lung, is usually associated with the presence of air or fluid in the pleural cavity, being due in the one case to disturbance of the natural pneumatic relations upon which normal inspiration depends, and in the other to direct mechanical pressure.

The appearances presented by limited areas of collapse on the surface of the lungs are quite characteristic. Each area is sharply defined, with an angular outline corresponding to that of the lobules affected, sunken below the surface, of a dark purplish colour, somewhat wedge-shaped on section, non-crepitant, and with a glistening surface. If there be also œdema, fluid will exude on pressure.

Symptoms.—Dyspnœa, more or less constant, and a varying degree of cyanosis, are the only symptoms which can be directly attributed to atelectasis. Recent collapse of any considerable tract of lung tissue of necessity adds gravity to the symptoms of whatever condition may have produced it, materially reducing, as it does, the extent of lung available for respiration. This is especially the case in broncho-pneumonia, of which affection atelectasis is an important feature.

Physical Signs.—When, as is usually the case, the areas of collapse are small and scattered irregularly through the lungs, no definite physical signs may be produced. If extensive, the breath sound is absent, and there may be dulness on percussion. When any considerable tract of lung—the whole of a lobe—has undergone collapse, a distinct depression of the chest wall may be present. In cases of collapse due to intra-pleural pressure, the place of the shrunken lung is taken by the fluid or air which has given rise to the condition, and hence no depression results. Within certain limits a collapsed area of lung is capable of re-expansion, especially in early life. When any plastic adhesive changes have been set up, this is no longer possible, and these changes are most prone to occur in lung tissue collapsed by actual pressure. Hence it frequently happens that the evacuation of fluid pent up for a long time within the pleura is not followed by recovery of the compressed lung, a result in part also due to the thickening of the visceral layer of the pleura, a change almost invariably found when fluid, even though it be a simple serous effusion, has been long present within the cavity. In collapse from plugging or spasm the absorption or removal of the obstruction may be followed by complete restoration of the lung tissue. A low form of pneumonia leading to fibrosis and bronchiectasis frequently follows collapse.

Treatment must be directed towards relieving or removing the conditions which have produced the collapse. Re-expansion may sometimes be assisted,

when urgent symptoms have passed away, by means of the inhalation of compressed air in a suitable apparatus (see AIR, COMPRESSED, THERAPEUTICS OF).
E. C. BEALE.

ATHETOSIS.—This name was given by Dr. Hammond, of New York, to a condition which sometimes follows hemiplegia, and is met with most often in children.

The word means "with no fixed position," and the condition is characterized by slow, involuntary, spasmodic, irregular, and continually changing movements of the paralysed hand and foot, but especially of the former. The fingers and thumb assume various peculiar positions due to spasm of the interossei and lumbricales, but extension of the middle phalangeal joints is most common. The foot is usually in the position of talipes equino-varus, with extension of the big toe. The movements occur during rest, but usually cease during sleep. They are increased by voluntary efforts, which they very much impede. Athetosis only occurs in cases in which some voluntary power has returned, and it accompanies the return of power. Two forms of the disease are observed—(1) In children, without anæsthesia of the affected parts. In such cases epileptic fits often occur in the athetosed limbs. The lesion is probably a thrombosis of the veins of the motor area of the cortex. (2) In adults, sometimes associated with hemi-anæsthesia, but not with epileptic attacks. In such cases the lesion is considered to be situated in the posterior third of the hinder limb of the internal capsule, and in the optic thalamus contiguous to it.

The disease is probably due to irritation of unstable grey matter.

The *prognosis* is unfavourable as regards the cessation of the movements.

Treatment consists of nerve tonics and sedatives, especially the bromides, which are particularly indicated if there be epileptic fits. The uninterrupted galvanic current, with the positive pole at the neck and the negative on the affected arm, is of service in some cases.

C. E. BEEVOR.

ATRESIA is an imperforate condition of some orifice or canal whose lumen should be patent. It may be the result of congenital malformation or of disease.

ATROPHY.—As atrophy of a part

manifests itself by diminution in size, and microscopically by diminution and often disappearance of its constituent elements, it may be defined as a retrogressive change in parts originally well formed and well grown. The causes most potent in inducing atrophy are (1) disuse, (2) diminished blood-supply, (3) injury to nerves, and (4) continuous pressure.

Among familiar examples of *atrophy from disuse*, mention may be made of the shrivelling of the ductus arteriosus, hypogastric arteries, and umbilical vein immediately after birth. After successful lumbar colotomy, the large bowel on the distal side of the artificial anus will become thin and wasted. In the stumps of limbs after amputation, the bones, muscles, nerves, and vessels become reduced in size; the contractile elements of the muscles are replaced by fat, or represented by collections of fatty and fibrous tissue. In amputations so planned that the patient can utilize the stump in walking this atrophy may be in a large measure prevented. After injury to the vas deferens the testicle will atrophy, and in some cases totally disappear.

Many examples of atrophy from disuse are really instances of *atrophy from diminished blood-supply*. It is a well-established fact that organs most frequently used have the best blood-supply—indeed, healthy function and efficient blood-supply go hand in hand. Instances are not wanting to illustrate atrophy from direct interference with the vessels distributed to an organ. Embolism of a branch of the renal artery will cause atrophy of a wedge-shaped portion of the kidney cortex corresponding to the distribution of the plugged vessel. Atrophy of the retina is caused by plugging its central artery, due either to embolism or extension of atheroma from the internal carotid to the ophthalmic artery. Badly adjusted trusses have been known to obliterate the spermatic artery and induce atrophy of the testis. Attempts have been made, by ligature of the nutrient artery, to utilize these effects in practice—*e.g.*, to reduce limbs of inordinate size, as in elephantiasis and congenital giant-limbs; also to check the growth of large tumours which were beyond the reach of legitimate surgery. In a few instances the results have been encouraging.

Atrophy from injury to nerves is seen in the wasting of muscles which follows division or injury of the dominant nerve or nerve centre, a condition of great

interest. Muscles are to be regarded as the peripheral end-organs of motor nerves, in the same sense that the retina is the end-organ of the optic nerve. The atrophy of the thumb muscles following division of the median nerve occurs too rapidly for us to attribute it merely to disuse. Many forms of muscular paralysis, and subsequent atrophy from injury to nerves, are of the utmost diagnostic value in clinical medicine. For example, pressure on the recurrent laryngeal nerve by a thoracic tumour induces atrophy of the principal laryngeal muscles. Atrophy of the muscles supplied by the left recurrent laryngeal nerve is the only constant pathological change found in the larynx of roaring horses. Wasting of one-half of the tongue following injury to the base of the skull is indicative of damage to the atlas or the occipital condyle, implicating the hypoglossal nerve. In paralysis of the fifth cranial nerve the muscles of mastication on the affected side waste more rapidly than when simply disused, as in cases of excision of the lower jaw.

There is an interesting form of this change to which the term "correlated atrophy" may be conveniently applied. In cases of successful amputation at the hip-joint or upper third of the thigh the corresponding os innominatum will become thin and light, the aorta narrower, and the heart distinctly smaller. Such changes are a combination of diminished use and limitation of blood supply. The change in the heart is what would be expected: it is a muscular organ developed according to the amount of work required of it, and as the lower limb represents about one-fourth of the total body weight, its removal ultimately diminishes the work which the heart is called upon to perform. When the operation is performed without much loss of blood, a remarkable tumultuous action of the heart may occur and last for several days. In medical practice this correlated atrophy may be well studied in the nervous system; destruction of the corpus striatum by hæmorrhage is followed by atrophy of the motor tract of the crus cerebri (crusta) and of the lateral tracts of the cord. These facts have been utilized by experimentalists to trace the course of the various tracts in the spinal cord. There is also reason to believe that, in old-standing cases of paralysis of the leg, diminution or atrophy of the convolutions occurs in the leg area of the motor region of the cerebral cortex. In the same group must be placed the atrophy of the anterior

quadrigeminal bodies when the eyes have been extirpated in young animals.

We have now to consider *atrophy from continuous pressure*. Among the many examples of this common form of atrophy may be mentioned the thinning of the skull bones in cases of intra-cranial tumours, especially cysts. The pressure of hydatid cysts lodged in the brain of sheep will produce holes in the bone, and allow the cyst-wall to project beneath the skin. The erosion of bone from the continuous pressure of aneurysms is a well-known example. Loose bodies in joints will often hollow out recesses in the heads of bones, and the continuous pressure exerted by the dislocated head of a femur or humerus will rapidly form a new, and often useful, joint-socket. It is by continuous pressure that cystic tumours of the abdomen often open into the intestine, rectum, or bladder; or cysts in opposite ovaries will unite and form intercommunicating chambers, and hydatid cysts open into the peritoneum.

As a physiological process atrophy manifests itself in a variety of ways. The modifications of larval forms furnish many wonderful examples—*e.g.*, the disappearance of the external gills in young sharks, in tadpoles, and the Alpine salamander; the loss of the tail in ascidian tadpoles, and in anurous batrachians; atrophy of the remarkable sucking disc in the young lepidosteus, and, returning to man, the disappearance of Peyer's glands in advanced life.

In the mammalian embryo atrophy from continuous pressure is responsible for the formation of a single median vessel from two parallel trunks; of a single median uterus from bilateral oviducts; of single ducts to an aggregation of glands, and for the communication of the third with the lateral ventricles of the brain.

From a physiological and pathological point of view atrophy is a process of much interest, and produces conditions of great importance in animal organizations of all kinds, from the simplest to the most complex.

J. BLAND SUTTON.

ATROPHIA CUTIS is a term applied to various changes in the skin characterized by the diminution or disappearance of certain of its elements.

Senile Atrophy is an expression of the general degenerative changes of advanced life. The skin is thin, loose, wrinkled from the absorption of subcutaneous fat, and generally discoloured.

Troublesome itching (*pruritus senilis*) is often complained of. The hair falls off, and the sebaceous glands are destroyed or blocked and distended, but the sweat glands are unaltered. Small, warty, brownish elevations, which can be detached by the finger-nail, are common on the trunk, neck, and arms (*verrucae seniles*).

The cases described as general idiopathic atrophy of the skin closely correspond to the hide-bound condition of diffuse scleroderma.

Lineæ Albicantes are the result of extreme stretching of the skin, and the consequent forcible separation of bundles of connective tissue, which become parallel to one another, and remain so. Minute hæmorrhages result from the rupture of blood-vessels, so that the lesions are at first pink and sometimes even raised, but after absorption of the blood, linear, glazed, white, atrophic scars are left. They are commonest on the abdomen of females as the result of pregnancy, on the mammae from lactation, but may be found over any form of prominent, rapidly formed tumour, and are frequently a striking feature in cases of diffuse lipomata.

Neuralgia, injuries to nerve-trunks, progressive muscular atrophy, tabes dorsalis, and acute rheumatism are sometimes accompanied or followed by a tropho-neurotic condition known as glossy skin. It chiefly affects the fingers, the skin of which becomes painful, pinkish, tightly stretched, glazed, and sometimes ulcerates. The nails are often involved; they become curved, their matrix exposed and ulcerated from retraction of the skin. Persistent neuralgia, especially of the fifth nerve, is sometimes followed by atrophic scarring.

Striæ Atrophicæ are lesions similar in all their objective characters to lineæ albicantes, but having no known etiology. They are commonest about the buttocks and thighs, and are probably due to perverted innervation.

Maculæ Atrophicæ are round or ovalish, white, depressed spots of thinned skin, varying in size from a pin's head to a threepenny-piece, most common in women about the neck and trunk. As they give rise to no subjective symptoms, their early stage is seldom observed; in it the spots are raised, hard, pinkish, or surrounded by a purplish, vascular halo, and, indeed, are identical with minute spots of scleroderma, with the localized or diffuse forms of which they are frequently associated. The disease is very chronic,

lasting for years, but tends to ultimate spontaneous recovery, the little depressed spots filling up almost completely.

In none of these affections is treatment of any avail. J. J. PRINGLE.

AUSCULTATION, or listening, is a means of diagnosis applicable to any of the internal organs of which function or movement produces sound. It is chiefly employed in the physical examination of the heart and lungs. Auscultation may be practised directly, by applying the ear to the chest wall, or mediately, by means of a stethoscope. The forms of stethoscope in common use are the rigid tube of wood, vulcanite, or metal, with broad ear-piece and narrow chest-piece, and the flexible, single or binaural, instrument. The first has the advantages of enabling the auscultator to appreciate any abnormal impulse of the heart or of an aneurysm, and also that it can be applied to the chest when covered with a layer of clothing, whereas the flexible instrument must be applied accurately to the skin itself. The binaural stethoscope, however, is more convenient for the examination of children and of patients in the recumbent position.

AUSCULTATION OF THE HEART.—Two factors are concerned in the production of the first sound of the heart—(1) the contraction of the ventricles, and (2) the closure and sudden tension of the mitral and tricuspid valves. The sound resulting from muscular contraction is long and low pitched, whilst that produced by the sudden tension of membranous structures, like the cardiac valves, is short and high pitched; the normal first sound is the resultant of these two factors. In disease, if the former element predominate, as in hypertrophy, the sound is prolonged and of low pitch; if, on the other hand, the muscular force be feeble and the cavities dilated, the sound, owing to the predominance of the valvular element, becomes short and high pitched. In the production of the second sound there are also two factors—(1) the closure of the aortic and pulmonary valves, and (2) the sudden tension of the aorta and pulmonary artery. If the blood tension in either vessel be raised, the elastic recoil will be more forcible, and a louder or *accentuated* sound will result. When the factors concerned in the production of either sound of the heart do not come into operation synchronously on the two sides, either sound may be double

instead of single, a condition to which the term *duplication*, or more commonly *reduplication*, is applied. It is a change frequently observed, and is probably due to alterations of tension either within the heart or in the aorta or pulmonary artery. If one of the normal sounds be replaced, or obscured by a sound having a blowing character, a *murmur* or *bruit* is said to be present, the name given to it corresponding with the period of the cardiac cycle in which it occurs. If in the period of auricular systole, it is termed *presystolic* or *auricular systolic*; if in that of ventricular systole, *systolic*; if during the diastole of the ventricles, *diastolic*; and should it immediately follow the first or second sound, *post-systolic* or *post-diastolic* (see HEART, DISEASES OF VALVES).

All murmurs should be timed by the carotid pulse, *not by their relation to the apex beat* (see PALPATION).

The following views as to the mode of production of murmurs are, it is believed, now generally accepted:—

1. All murmurs are due to sonorous vibrations occurring in the blood stream, the result of friction of the particles of the blood against each other.

2. This friction is induced by eddies or oscillations, which originate during the passage of the stream through a narrow into a wider part of the vessel.

3. Murmurs are primarily independent of the condition of tension of the structures forming the orifice, and are chiefly affected by the rapidity of the flow.

4. The primary vibrations in the stream may be varied by certain conditions of the orifice and valves.

5. These primary vibrations may produce secondary vibrations in the containing vessel and neighbouring parts.

The most frequent cause of murmur is some change in one of the cardiac valves permitting of reflux into the cavity which it guards, or producing a narrowing of the orifice.

Cardiac murmurs may also be present without structural change in the valves or orifices, especially in anæmia and chlorosis, and, when the action of the heart is excited. Such sounds are termed *anæmic* or *hæmic* and *functional* murmurs respectively.

Hæmic murmurs are described in the article on CHLOROSIS.

Sounds closely resembling those resulting from organic disease of the valves, but really produced outside the heart, are of frequent occurrence, and are termed *false* or *cardio-pulmonary* murmurs.

The various conditions which may give rise to these murmurs may be classified thus:—1. Displacement of, or pressure upon, the heart, the result of disease of the (a) lung, (b) pleura, (c) thorax, or (d) abdomen. 2. Effusion into the pleural cavity. 3. Changes in the pleura of the præcordial area. 4. Changes in the lung overlying the heart. 5. Changes in the pericardium.

1. (a) *Displacement of the Heart, the Result of Disease of the Lung.*—As a result of the contraction of a cavity, say in the apex of the left lung, the heart is frequently found displaced upwards. Under these circumstances a systolic murmur is often heard in the second or third left interspace, having its maximum intensity about 2 inches from the edge of the sternum. The presence of the cavity, and of the indurated lung surrounding it, intensifies the murmur, which may be so distinct as to be audible over the greater part of the left chest. This sound, though more commonly suggesting aortic disease or a hæmic murmur in the pulmonary artery, may be mistaken for the murmur of mitral regurgitation. When the presence of the cavity is detected and the displacement of the heart recognized, the differential diagnosis should not be difficult, especially when the somewhat rare association of phthisis and valvular disease is borne in mind.

- (b) *Pressure upon the Heart, the Result of Disease of the Left Pleura.*—Perhaps of all the false murmurs none are more common, or present greater difficulties in diagnosis, than those caused by pressure upon the heart resulting from the contraction of the left side of the chest after an attack of pleurisy. The pleura is probably thickened, and the lower lobe of the left lung partially collapsed, and at each systole a sound is produced by the sudden impact of the heart displacing the air in the larger bronchi. This may be audible not only at the apex and in the axilla, but also at the angle of the left scapula, in the trachea, and in the mouth.

In one case observed by the writer, a systolic murmur produced in this manner was distinctly audible at a distance of more than a yard from the patient. In this case an aneurysm of the aorta with pressure on the trachea had been suspected. This murmur may be present even during attacks of functional palpitation.

- (c) *Displacement of the Heart from Deformity of the Chest.*—Murmurs originating from this cause are occasionally met

with. In a case under the care of the writer the lower part of the sternum was depressed to such an extreme degree that by careful measurement it was clear that its posterior surface was only separated from the spine by a distance of about two inches. The chest was shaped like a crescent with blunted horns, the left one holding the heart, which could be, so to speak, grasped by the hand and all its movements distinctly felt. In that case a loud systolic murmur was present.

(d) *The Upward Pressure of a Large Effusion into the Peritoneal Cavity* is sometimes the cause of a false murmur, systolic in time, and audible at either the base or apex of the heart. When the fluid is withdrawn by paracentesis, the murmur disappears.

2. *Effusion into the Pleural Cavity*.—In some cases of pleural effusion, more frequently when the left side of the chest is affected, a loud and prolonged systolic murmur may be heard either near the apex or at the base of the displaced heart. Such a condition is likely to produce a murmur either in the pulmonary artery or in the aorta by pressure upon the vessel, or, what is more probable when the murmur is localized at the apex, within the ventricle itself. The murmur completely disappears on the removal of the fluid from the chest.

3. *Changes in the Pleura of the Præcordial Area*.—The sounds simulating cardiac murmurs resulting from this cause will be found described under FRICTION SOUNDS.

4. *Changes in the Lung overlying the Heart*.—In the subjects of pulmonary phthisis it is very common to hear a systolic murmur about the apex of the heart which closely resembles the murmur of mitral regurgitation. The sound is caused by the impact of the heart upon lung tissue partially consolidated, producing an audible sound by displacement of the air in the bronchi in a similar way to that already described. It is almost always most distinct during expiration, is superficial, high pitched, and disappears when the breath is held after a deep inspiration, and often becomes inaudible when the patient lies down. This murmur may sometimes be heard in the axilla and at the angle of the left scapula. The most common site of a murmur thus produced is not, however, at the apex of the heart, but in the second left intercostal space, about 2 inches from the sternum. In doubtful cases of early phthisis of the left upper lobe, the pre-

sence of this morbid sound is strongly suggestive of lung consolidation. In many of these cases, however, it is possibly due to some displacement of the pulmonary artery, the result of the disease of the neighbouring lung.

5. *Changes in the Pericardium*.—The characters of the pericardial friction sound are described under FRICTION SOUNDS and in the article on DISEASES OF THE PERICARDIUM. False murmurs, when due to chronic changes in that membrane, are frequently heard at one particular spot—viz., the sixth left interspace and over the seventh rib close to the base of the ensiform cartilage. Here the right ventricle is in contact with the chest wall, and it is on its anterior surface that the “white patch” is most commonly found. The sound produced by the movement upon each other of the pericardial surfaces at this spot is systolic in time, usually short, sharp, localized, and superficial; it seldom acquires a blowing character. In fact, it often resembles more nearly a rough re-duplication of the first sound than a murmur. It is perhaps doubtful whether the altered sound, which is so commonly heard at this spot, is in all cases due to the presence of a “white patch” on the pericardium. It is especially common in emphysema with downward displacement of the heart. The effect of change of position upon this murmur is variable. It may disappear entirely when the patient is in the recumbent position, as often happens with friction sounds audible elsewhere over the heart, whilst at times it is hardly at all affected by such a change. When the heart is not displaced, a murmur presenting similar characters may often be heard in the fifth left interspace close to the sternum. Thickening of the pericardium of the left auricular appendix occasionally produces a rough systolic murmur in the second left interspace.

The following precautions should be observed in the examination of all cases presenting murmurs. Assuming that the presence or absence of those consecutive changes in the heart which are almost invariably associated with disease of any given valve has been noted; if there be still room for doubt, the following points must be observed carefully:—

1. The exact period in the cardiac cycle occupied by the murmur. False murmurs are often not exactly synchronous with the commencement of systole or diastole; they may precede or follow the one or the other.

2. The site of maximum intensity and the line of conduction of the murmur. These do not usually coincide with what is found with similar murmurs of organic origin.

3. The condition of the lungs. With doubtful apex murmurs evidence of pulmonary engorgement is strongly in favour of organic valve disease, as that condition is almost invariably absent in the reflux of anæmia.

4. The effect of change of position upon the sound. *It is essential to examine every case of suspected valve disease both in the standing and recumbent position.* It may be stated with confidence that an opinion given in a doubtful case without observing this precaution is of no value. Functional and false murmurs often disappear when the patient lies down, whilst an organic murmur, especially that of mitral stenosis, may be only audible in that position. A murmur which suddenly and completely disappears when the patient lies down, provided there be not at the same time any marked alteration in the pulse-rate, is almost certainly not due to organic disease of a valve.

5. It is important in all cases to auscultate the trachea. A murmur audible in the trachea may be due either (1) to the conduction of the murmur of aortic stenosis; or (2) to the impulse of an aneurysm; or (3), to the impulse of the heart causing an air wave in the bronchi and trachea, this latter being by far the most common cause of tracheal murmurs. Mitral murmurs are not audible in the trachea.

6. False murmurs often disappear completely when the breath is held.

7. The state of the pulse may at once negative a suspicion of organic disease founded on the presence of a murmur.

J. K. FOWLER.

AUSCULTATION OF THE LUNGS (BREATH SOUNDS).—It is a misfortune to medicine, a reproach to those who practise it, and a source of great difficulty to students, that the nomenclature of the auscultatory sounds should be in such a state of confusion. As uniformity in this respect can only be obtained by sinking individual preferences and submitting to the dictates of authority, the terminology recommended by the majority of the contributors to the Provisional Report of the Committee of the International Medical Congress has been adopted in this and the following article.

A knowledge of the normal breath sounds is obviously an essential preliminary to the auscultation of the chest in disease. This can only be obtained by the examination of a large number of healthy subjects. Three varieties of respiratory sounds are to be recognized in every healthy chest—(1) the sound produced in the glottis, and audible over the lower end of the trachea, which is termed “tracheal” or “bronchial” breathing; (2) the sound produced in the alveoli and audible over the lungs, termed “vesicular” breathing; (3) the sound audible about the roots of the lungs which combines the characters of the two preceding, and is termed “broncho-vesicular” breathing. As the normal respiratory sounds vary considerably in intensity in different individuals, there is no common standard of reference, and one side of the chest must always be compared with the other. Any change in the *quality* of the sounds, however, is to be regarded as abnormal.

The varieties of respiratory sounds, normal and abnormal, may now be more fully described:—

Vesicular Breathing.—This is a soft rustling sound audible during inspiration. It is generally followed, without any appreciable interval, by a fainter sound, of shorter duration, and blowing quality, heard during expiration; but this may be absent. The two sounds constitute the normal respiratory murmur audible over the healthy lung.

Prolonged Expiration.—The expiratory sound may be prolonged—a sign the significance of which varies with the pitch and quality of the sound. If high pitched and bronchial or tubular in quality, it indicates consolidation of the lung; if, on the other hand, the pitch be low and the quality faintly blowing, but not bronchial or tubular, emphysema is probably the cause, or it may be due to the presence of a cavity in the lung, either distant or of small size.

Exaggerated Breathing.—This is a sound possessing the characters of vesicular breathing in an exaggerated degree. It is the normal breath sound of children, but when met with in adults indicates that an increase of function in one part is compensating for deficient action elsewhere.

Exaggerated breathing is perhaps best heard over the unaffected side in cases of pleural effusion.

Diminished Breathing.—The characters of the normal breath sound are retained, but the intensity is much diminished. It

is present under a variety of conditions, involving lessened functional activity of the lung, and very commonly at the apex in the early stage of phthisis.

Suppressed Breathing.—The breath sound is absent, a condition met with in cases of pleurisy with effusion, also in certain cases of pneumonia, when the bronchi are filled with exudation (massive pneumonia), and in complete occlusion of a bronchus from any cause.

Interrupted Breathing: Wavy or Cog-wheel Breathing.—The inspiratory sound is divided into two or three parts, owing to an irregular expansion of the lung, the result of disease of either the bronchi or the lung interrupting the entrance of air, or of irregular contraction of the muscles of respiration. It may be heard at the apex of the lung in phthisis, but is an untrustworthy sign owing to its close simulation by the breath sound present in certain nervous conditions. It is also occasionally simulated by a succession of "air-wave" murmurs (cardio-pulmonary) produced by the impact of the heart upon the lung.

Bronchial Breathing is the glottic sound, as heard in the normal chest near the lower end of the trachea, over the seventh cervical spine. The sound there audible may be taken as the standard of comparison by which to gauge the quality of similar sounds heard elsewhere in the chest of the same patient, the term "bronchial breathing" being used to signify that the sound heard over an area of disease in the lung is of the same quality as that audible over the seventh cervical spine. It is of variable intensity, and differs from vesicular breathing in that the inspiratory sound is higher in pitch and tracheal in quality, whilst the expiratory sound is separated from the former by a distinct interval, is tracheal in quality, usually more intense, and of equal or longer duration.

When heard in phthisis or pneumonia it signifies the presence of consolidation in an area of lung; in large pleuritic effusions it may be audible over the site occupied by the lung, and indicates that it is compressed or collapsed. It is occasionally audible over the whole of the affected side in cases of pleural effusion, especially in children; when so audible in the case of adults it is considered by some writers to indicate the existence of positive intra-thoracic pressure; as, however, it is occasionally present in cases of moderate effusion in which there is no displacement of the heart, that statement cannot be absolutely accepted. It

probably indicates that the large bronchi of the collapsed lung are still patent. When a thoracic aneurysm or mediastinal growth is situated between a large bronchus or the trachea and the chest wall, bronchial breathing is often audible over the area occupied by the tumour.

Broncho-vesicular Breathing, as the name implies, combines the characters of bronchial breathing with those of the normal respiratory sound, and indicates the presence of an amount of consolidation short of that necessary to produce bronchial breathing. It is heard normally over the sternal portion of the infra-clavicular regions in front and the upper part of the inter-scapular region behind. In the inspiratory sound the vesicular quality is diminished, but not absent; the tracheal quality is more or less marked, according to the degree of consolidation; the pitch is raised in proportion as the tracheal quality predominates over the vesicular; the intensity is variable.

The pitch, tracheal quality, and length of the expiratory sound correspond with the characters of the inspiratory sound.

Tubular Breathing is the glottic sound conducted through an area of lung completely consolidated.

Tubular breathing and bronchial breathing are often used as synonymous terms, but the former sound differs from the latter in possessing a "whiffing" character and in its higher pitch.

It is heard typically in lobar pneumonia, when the bronchi are patent; when present in phthisis, it usually indicates that a portion of lung situated near the surface is *completely* consolidated, the bronchi being patent.

Cavernous Breathing is a modification of the glottic sound produced by the presence of a cavity within the lung or external to it, in communication with an open bronchus.

The inspiratory sound is low pitched, hollow, and blowing; the expiratory sound is still lower in pitch, has the hollow, blowing character more marked, and is usually more prolonged.

It requires a partially empty cavity, in communication with an open bronchus, and at least equal in size to an unshelled walnut, to produce a breath sound of this character.

The breath sound audible over the supposed cavity should always be compared with that over the lower end of the trachea, as errors in the diagnosis of

cavities are of frequent occurrence owing to the neglect of this precaution.

Amphoric Breathing is a sound of variable intensity presenting the hollow blowing character of cavernous breathing, in an exaggerated degree, and with the addition of a distinctly "metallie" quality.

It indicates the presence of a large cavity either in the lung or external to it in the pleura, in communication with an open bronchus.

The differences between vesicular, bronchial, tubular, cavernous, and amphoric breathing may be expressed in tabular form thus:—

Vesicular Breathing.

(I. = inspiration; E. = expiration.)

	Pitch.	Quality.	Interval.	Duration.	Intensity.
I.	low	vesicular	none	E. shorter than I. or	variable
E.	lower	blowing		absent	faint or absent

Bronchial Breathing.

I.	high	tracheal (seventh cervical spine)	distinct	E. equal to or longer than I.	variable
E.	higher	do.			greater

Tubular Breathing.

I.	higher than in Br. br.	laryngeal or whiffing	distinct	E. equal to or longer than I.	variable
E.	higher	do.			greater

Cavernous Breathing.

I.	low	blowing and hollow.	distinct	E. longer than I.	variable
E.	lower	both characters more marked.			greater

Amphoric Breathing.

I.	low	hollow and metallic	distinct	E. longer than I.	variable
E.	lower	both characters more marked			greater

J. K. FOWLER.

AUSCULTATION OF THE LUNGS (ADVENTITIOUS SOUNDS).—A great variety of sounds to which, as a whole, the above term is applied become audible in diseased conditions of the lungs, bronchi, and pleura:

Friction Sounds will be found described under that heading.

Rhonchi are dry musical sounds produced in the bronchial tubes. When low pitched, loud, and snoring in character, they are termed *sonorous rhonchi*; when high pitched and whistling, they are called *sibilant rhonchi*; the pitch of the sound being chiefly dependent upon the calibre of the tube in which it is produced. Sonorous rhonchi usually indicate that mucus is present in the large tubes; sibilant rhonchi, that the lining membrane of the smaller bronchi is swollen. The former often disappear when the patient coughs; the latter are usually uninfluenced by cough.

Rhonchi may be audible during either inspiration or expiration, or may accompany both parts of the respiratory act; in bronchitis they are often especially marked during expiration.

Stridor is a harsh vibrating sound resulting from obstruction of the larynx, trachea, or a main bronchus. This sound may be caused by a variety of local conditions, but is most often due to compression of the trachea by an aneurysm, an enlarged thyroid, or an intra-thoracic tumour. Paralysis or spasm of the vocal cords, the result of pressure on the recurrent laryngeal or pneumogastric nerves and cicatricial changes within the larynx or trachea, may also produce stridor.

Râles are moist sounds produced by the bubbling of air through fluid in the alveoli or bronchi, and by the separation of the moist surfaces of the swollen mucous membrane. They vary much in character, being chiefly influenced by the condition of the lung, as regards sponginess, consolidation, softening, or excavation, in the neighbourhood of which they are produced. The presence of consolidated lung gives a sharp, crackling, explosive quality to the sound, whereas, when the surrounding lung is of spongy texture, the sound is usually of a bubbling character. Sounds of the first variety are termed (1) small, (2) medium, and (3) large crackling râles.

(1) *Small Crackling Râles* are sharply defined crackling sounds of small size, chiefly audible during inspiration, but also during expiration.

They indicate the presence of fluid in

the finer bronchi, the surrounding lung being usually consolidated. Sounds of this character are present when a tubercular deposit or pneumonic exudation is undergoing softening.

(2) *Medium Crackling Râles* are sounds presenting the same general characters as the above, but of larger size. They are met with under the same conditions.

(3) *Large Crackling Râles* are sounds produced at the site of softening in the lung when the process has extended to such a degree that small cavities, the size, perhaps, of a pea or hazel-nut, have formed, the surrounding lung being still consolidated. They are usually fewer in number than either of the former varieties. Râles of this character are of frequent occurrence in phthisis, and are also heard when a pneumonic area is breaking down.

Moist sounds produced in the neighbourhood of spongy lung are termed (1) small, (2) medium, and (3) large bubbling râles.

(1) *Small Bubbling Râles* are sounds differing from the corresponding râle of the former variety in that they are less sharply defined, and suggest the bursting of a soft bubble rather than the explosion of a minute shell. They are produced by the passage of air through mucus in the bronchioles, the surrounding lung being of spongy texture. Sounds of this character are heard in cases of capillary bronchitis, especially in children.

(2) *Medium Bubbling Râles*.—These sounds are similar in quality to those above described, but are produced in larger tubes, and are therefore of larger size.

(3) *Large Bubbling Râles*.—The character of these sounds is almost sufficiently indicated by the name. They are produced in the larger bronchi and trachea by the passage of air through frothy mucus, and are heard in cases of bronchitis and pulmonary engorgement when the vital powers are failing.

Gurgling.—Large liquid sounds of a character indicated by the name, produced in a cavity in the lung, and best elicited by making the patient cough.

Clicking Sounds.—The character of these sounds is best illustrated by whispering the word "click." They differ from râles in being sticky rather than moist in quality; they are produced during inspiration only, and are most often heard at the apex of the lung in phthisis. The presence of "clicks," as they are generally termed, indicates the com-

mencement of softening in a tubercular deposit.

These sounds are not distinguished by German writers from crackling râles, and it must be admitted that the difference is but slight and with difficulty appreciated by students of auscultation.

Crepitation is a sound almost exactly similar to that produced by rubbing the hair between the fingers close to the ear.

The use of the term should be strictly limited to sounds of this character—*i.e.*, to the sense in which it was employed by Laennec.

Crepitation is caused by the passage of air into vesicles either containing a fibrinous exudation or in a condition of collapse.

It is heard typically during the latter part of inspiration in the early stage of pneumonia, and also at the bases of the lungs when in a state of œdema, lobular collapse, and hypostatic pneumonia.

Metallic Tinkling.—When a moist sound is produced in a large, dense, walled cavity (pulmonary or pleural), or in a neighbouring bronchus in communication with it, the sound acquires a peculiar quality, which is best described by the terms "metallic" and "tinkling."

Succussion Splash.—A peculiar splashing sound, described by Hippocrates, is produced by the sudden movement of air and fluid in a cavity. It is present in cases of hydro- or pyo-pneumothorax, and is elicited by shaking the patient or making him cough.

Bell Sound.—When air is present in the pleural cavity (pneumothorax), if a coin placed flat upon the chest be struck with another coin, a sound like the tinkling of a bell will be audible through the stethoscope applied over the affected area.

J. K. FOWLER.

AUSCULTATION OF THE VOICE (Vocal Resonance).

—The voice sounds, as heard over the healthy lung, are diffused, distant and low pitched. They vary in intensity in different individuals, being chiefly dependent upon the quality of the voice. They are *diminished* in intensity by the intervention of any badly conducting medium between the lung and the chest wall, a condition present in pleurisy with effusion, in thickening of the pleura, and in pneumothorax; by occlusion of the bronchi, owing to the presence of morbid growths in the lung or mediastinum; or of solid fibrinous exudation filling the tubes, as occasionally occurs in croupous pneumonia (massive pneumonia); and by the

extremely spongy condition of the lung present in emphysema. The voice sounds are *increased* in loudness, but without alteration in pitch, when a degree of consolidation of the lung is present insufficient to produce bronchophony, or when the voice is transmitted through a cavity not surrounded by consolidated lung (Flint). The vocal resonance is normally more intense in the neighbourhood of the trachea and large bronchi than elsewhere, and in the right infra-clavicular region than in the left. The conduction of the whispered voice is modified by the same conditions which affect the loud voice, and in a similar manner.

Bronchophony is a sound of variable intensity characterized by concentration of the transmitted voice, elevation of pitch, and a degree of nearness to the ear, falling short of the condition requisite for pectoriloquy—*i.e.*, the sound, though seeming to originate near to the end of the stethoscope, passes away from the observer, and does not appear to have been spoken from the end of the instrument straight into his ear. Bronchophony is usually found with bronchial breathing, and has the same significance. It is normally present over the lower cervical spines, in the upper part of the inter-scapular region, and over the sternal portion of the infra-clavicular regions.

Pectoriloquy is by some writers considered to be merely an exaggerated de-

gree of bronchophony. It differs from it, however, in the fact that, whilst in the latter the *noise* only is transmitted, in pectoriloquy *articulate speech*, in addition to sound, becomes audible. Pectoriloquy has been divided into "bronchophonic pectoriloquy" and "cavernous pectoriloquy," the one form indicating the presence of consolidation of the lung, the other, of a cavity. If pectoriloquy be accompanied by the characters of bronchophony (nearness to the ear and elevation of pitch) the transmission is by solidified lung; if, on the other hand, speech be transmitted and the characters of bronchophony be wanting, the inference is that the pectoriloquy denotes a cavity (Flint). If words articulated in a whisper be conveyed to the ear of the auscultator, *whispering pectoriloquy* is said to be present. The sign has the same significance as pectoriloquy of the loud voice.

Ægophony is a term applied to a modification of the vocal resonance in which the transmitted sound has a nasal or bleating character. It occurs in pleurisy when the amount of effusion is but moderate, and is most often heard about the angle of the scapula. It is believed by Dr. Stone to depend upon the interception by the exudation of the fundamental vowel tone and the passage of the harmonic overtones.

J. K. FOWLER.

B

BATHS.—Bathing consists in the application of liquids, vapours, or gases—generally or locally—to the surface of the body. The fluid employed for the purpose may be simple, or variously medicated by different substances held in solution or in suspension; and more than one form of bath may be combined in the same application. According to its nature and method of administration, the bath may be heating or cooling in its effects; stimulant, tonic, sedative, depressant, or locally alterative: it always exerts a more or less cleansing and detergent action upon the skin.

Immersion in fresh water constitutes the simplest form of bath; and water in some form is the vehicle by which are applied most of the various other substances which distinguish the several medicated and composite baths.

A. LIQUID BATHS.—The *Cold Bath* has

a temperature below 70° Fahr. The immediate effect of its application is to produce a sensation of cold, gasping respiration (reflex action), and pallor of the skin, with subsequent reaction. Prolonged immersion increases the loss of temperature, and induces vital depression, not followed by reaction, and only slowly recovered from even on removal from the bath. The remote effect of the cold bath, if not too prolonged, is to increase the rate of tissue change and the excretion of urea and carbonic acid; and hence it acts as a general tonic and as a stimulant to the appetite.

The *Tepid Bath* ranges from 85° to 95° Fahr. It acts mainly upon the skin as a sedative, emollient, cleansing, and detergent agent; the pulse, respiration, excretion, secretion, and body-heat are practically unaffected.

The *Warm Bath*, at from 95° to 104°

Fahr., slightly increases the activity of the circulation, and somewhat retards tissue metamorphosis; it is a valuable soothing agent, but in other respects its effects on the system are almost inappreciable.

The *Hot Bath*, at a temperature of from 104° to 110° Fahr., affects mainly the nervous and circulatory systems: it greatly increases the frequency of both pulse and respiration, and is followed by a free perspiration. Special ends are subserved by such partial applications as the hip-bath and the foot-bath.

The effect of any bath upon the skin is much increased by brisk friction both during and after immersion.

The duration of any kind of bath must depend on the age and condition of the bather and the object which it is desired to attain. Cold baths are fitted for the vigorous and healthy, but should never be taken when exhausted, or immediately after a full meal, or if there be reason to suspect congestion of any internal organ. The weakly and debilitated may combine many of the advantages of both the tepid and the cold bath by immersion in, or sponging with, warm water, followed (while still standing in warm water) by the rapid application of a spongeful of cold water to the general surface, or at least to the throat and chest. Asthenic persons should avoid baths, or the immersion should be of the shortest possible duration, and those suffering from any degeneration of the heart or vessels should avoid all but tepid baths. The excessive employment of hot baths exercises a weakening effect upon the system.

The simple liquid bath may be variously medicated, as in the

Sea-water Bath.—This is more stimulant and tonic in its effects than fresh water, and hence is useful in convalescence, in chlorosis, and in strumous disease. It may be given as a cold, tepid, or hot bath, according to circumstances. Sea-water contains about 3 per cent. of soluble salts, and (as regards the action of the solution itself) an efficient substitute can be obtained in inland places by dissolving bay-salt, Tidman's sea-salt, or even common or rock-salt in fresh water. About 4 to 9 lb. of salt may be dissolved in 30 gallons of water, according to the degree of stimulant effect desired. Half a pound of bay-salt dissolved in 4 gallons of cold or tepid water makes a good salt-water sponge bath, to be used every morning, and followed by vigor-

ous rubbing with a flesh-brush or coarse towel.

Acid Bath.—This is considered useful in certain cases of dyspepsia, with sluggish liver and constipation. For a general bath 3jss of nitric acid and 3j to 3iij of hydrochloric acid are added to 30 gallons of warm water in a wooden or earthenware vessel. The patient should remain immersed for about ten to twenty minutes. The more convenient foot-bath is prepared by adding ½ ounce of nitric and 1 of hydrochloric acid to 4 gallons of warm water in a wooden or earthenware vessel; the feet should remain immersed for from twenty to thirty minutes, while the groins, axillæ, and hepatic region are sponged with the solution. This bath is to be used every alternate day for two or three weeks at a time.

Alkaline Bath.—Add 3 ounces of carbonate of potassium, or 6 ounces of carbonate (not bicarbonate) of sodium to 25 or 30 gallons of hot water. It is used in chronic squamous skin diseases, chronic rheumatism, and in lithæmic cases, &c., and should be prepared in a wooden, earthenware, or enamelled bath, as ordinary paint is rapidly affected by it.

Corrosive-sublimate Bath.—This is made by adding hydrargyri perchloridi 3iij and acid hydrochlor. 3j to 30 gallons of water. This bath is sometimes useful in secondary syphilis and in certain skin diseases.

Creasote Bath, used in squamous skin diseases: creasote 3iij, glycerine 3iv, aq. Cxxx.

The following soothing and emollient baths are serviceable in squamous and irritable conditions of the skin; the ingredients are in each case to be added to 30 gallons of water:—

Bran Bath: Boil 1 pound of bran in 1 gallon of water; strain the liquor, and add it to the bath.

Borax Bath: Borax 3iv, glycerine 3iij.

Gelatine Bath: Dissolve 1 pound of common glue in hot water, and add the solution to the plain bath, or to the bran bath, as above.

Starch Bath: Starch 1 pound.

Starch and Conium Bath: Add extr. conii 3j to the starch bath.

The *Iron Bath* (ferri sulphat. 3ss, aq. Civ) is valuable for strumous or rachitic children; it should be used in an earthenware or wooden vessel.

The *Mustard Bath* is a valuable stimulant; it is made by enclosing 2 to 4 ounces of ordinary mustard in a piece of muslin or thin linen and "swishing" it about in 4 gallons of hot water until the latter

becomes yellow. This may be used as a general bath for infants suffering from collapse, convulsions, severe bronchitis, &c.; as a foot-bath for adults in congested conditions of the lungs and brain, or to invigorate a languid circulation; and as a sitz-bath in some cases of amenorrhœa, &c. A child may remain in such a bath until the skin becomes distinctly reddened.

The *Pine Bath* is prepared by adding a decoction of pine-needles—or, more easily, by dissolving some of the commercial pine-extract, or pine-essence, in hot water; it is mildly stimulating, and is employed in hysteria, gout, and rheumatism.

The *Sulphur Bath*: Potassium sulphide $\frac{3}{4}$ iv to $\frac{3}{4}$ viii in 30 gallons of water; a little sulphuric acid may be added. Used in certain skin diseases, in scabies, lead colic, and lead palsy.

All the above baths should be taken warm—i.e., at a temperature of from 95° to 100° Fahr.—and their duration must depend upon the condition of the patient and the object of the treatment.

B. VAPOUR BATHS.—In these the skin is exposed to the action of steam, either alone or combined with the vapour of other substances, which are volatilized at the same time. The vapour bath may be applied, by means of a suitable apparatus, to a limited portion of the body only; or to the whole surface except the head; or the patient may inhale the vapour within a closed apartment, the whole surface being at the same time exposed to its influence, as in the common Turkish and Russian baths. In the vapour bath a higher temperature can be borne than in the hot-water bath, though for a shorter time, since the circum-ambient vapour interferes with heat radiation from the body. The chief value of the simple vapour bath lies in its power of provoking very profuse perspiration, thus relieving the lungs and kidneys and effectually cleansing the skin. An effective form of the

Simple Vapour Bath is readily extemporized by placing a pan containing 3 or 4 inches of boiling water beneath a cane-bottomed chair, on which the patient sits naked; a large blanket, which may be covered by a mackintosh, is thrown over all, and fastened round the neck; one or two red-hot bricks are then placed in the water, and generate abundant vapour. When the perspiration slackens, the skin should be energetically rubbed with a warm dry flannel, and the patient

should retire to bed, clothed in a flannel nightgown.

The *Calomel Bath* and the *Mercurial Vapour Bath* are administered in the same manner—either *locally*, the mingled fumes of the volatilized mercurial salt and of water vapour being directed to some particular region of the body by means of a suitably constructed apparatus; or *generally*, as follows:—The patient sits on a cane-bottomed chair, beneath which are placed two pans, each heated by a spirit-lamp; a flannel-lined oil-cloth or waterproof sheet is thrown over all, and is fastened round the patient's neck. One pan contains boiling water, and the other $\frac{3}{4}$ j to $\frac{3}{4}$ iiij of the bisulphide or of the grey or red oxide of mercury, or 20 to 30 grains of calomel. The skin is thus exposed to the combined action of hot air, steam, and of a volatilized salt of mercury. After a few minutes, perspiration breaks out, and soon becomes excessive. At this stage both lamps are extinguished, and when the patient becomes moderately cool, he puts on a night-shirt and goes to bed. If the full action of mercury be desired, the skin should not be rubbed after this bath. Such combined vapour baths have been largely used in the treatment of secondary syphilis.

C. GASEOUS BATHS are administered after a method similar to that of vapour baths.

The *Hot-air Bath* may be employed in either of two ways, the difference depending upon whether the patient does or does not breathe the heated air. A simple form of the latter kind of hot-air bath can be arranged by seating the patient on a chair, &c., exactly as described for the vapour bath, except that a spirit-lamp only is lighted beneath the chair, no water being employed; or the hot vapour may be introduced by a tube from a suitable apparatus beneath the bed clothes, which are tucked in round the neck of the patient, and secured from contact with his body by some sort of framework or "cradle."

When taking a hot-air bath of the first kind, the patient, after undressing, enters first a room called the *Tepidarium*, the air of which is at a temperature of from 112° to 117° Fahr., and remains there until free perspiration breaks out; he then passes to the *Calidarium* or *Sudatorium*, which is heated by hot pipes to about 130° or 140° Fahr., there he remains for from ten to fifteen minutes; he is then rubbed down and shampooed, after which he is bathed with water at about

85° Fahr. in the *Lavacrum*; then the whole body is soaped and rinsed, and finally the patient reclines on a couch in the cooling-room or *Frigidarium*, until the skin is again quite dry, when he proceeds to dress.

Hot-air baths can be borne of a much higher temperature than vapour baths; they do not so much impede respiration, they provoke more profuse sweating, and raise the temperature of the body to a greater extent.

Hot-air and vapour baths are useful in inducing increased action of the skin, and in catarrhal, neuralgic, and rheumatic conditions. They are effective in reducing some forms of obesity, temporarily at all events, and may be applied locally to rheumatic limbs and enlarged joints with advantage.

The hot-air and vapour, or Turkish, bath is contra-indicated if there be any obstruction to the circulation, if there be fatty degeneration of the heart or vessels or a tendency to vertigo or syncope, and in advanced life, as well as for women during pregnancy and menstruation.

The *Sulphurous-acid Bath* is a means of applying the fumes of burning sulphur to the body. The patient is seated on a cane-bottomed chair, and a blanket or an oil-cloth is thrown round him, the head remaining uncovered. On the floor beneath the chair stands a pan containing a little water. In this is placed a smaller vessel containing brimstone in small pieces, over which a little spirit of wine is poured, and then ignited. The sulphur takes fire, and burns, with the production of sulphurous-acid gas. After using this bath, the patient should at once be removed to another apartment while the doors and windows of that in which the bath has been taken are opened.

The *Sand Bath* is a useful method of applying dry heat—by means of heated sand—to enlarged and stiffened joints in cases of chronic rheumatism.

Many different kinds of medicated and composite baths are available at various health-resorts noted for the natural springs—hot, tepid, alkaline, sulphurated, &c.—which severally distinguish them.

C. E. SHELLY.

BERI-BERI.—A disease widely spread over certain tropical regions, and especially prevalent in India, in Ceylon, on the Malabar Coast, on the East and West Coasts of Africa, and in China and Japan. It is endemic in certain areas, but those who are the subjects of it recover on removing to a non-infected district. It

is believed by some writers to be due to a bacillus, but it is certain that diet has a large share in its causation, and it has been shown that deficiency of nitrogen and an excess of carbo-hydrates in the food are conditions most favourable for its appearance. One form of the disease is thought by some authors to depend upon the presence in the alimentary canal of parasites, especially the *doehmius duodenalis*, and possibly also the *trichocephalus dispar*. It appears in a chronic and acute form. The first symptoms are a sense of fatigue and numbness in the legs, with loss of the knee jerks, followed by paralysis of the extensors, first of the feet, then of the hands, and muscular tenderness. The pulse is very rapid. There is neither fever nor albuminuria, but the patients are anæmic and at the base of the heart hæmic murmurs are often audible. There may be anasarca of the legs, followed by effusions into the pleura and pericardium; or dropsy may be absent, in which case the skin is very dry, and the muscles are seen to be wasted. The acute form of the disease is generally fatal, death often occurring from dropsy; but in the chronic form recovery frequently takes place. A person who has once had an attack is liable to another the next year. The disease is much more common in men than in women.

Treatment.—A strict attention to the diet is the best preventive; the dropsy should be treated on general principles.

BILE, THE.—The bile is secreted by the liver, and is poured out by the bile ducts into the duodenum. It is a golden-yellow or yellowish-green, clear, slightly viscid fluid, with an intensely bitter taste; its reaction is feebly alkaline, and its density is from 1026 to 1032.

The quantity is increased by digestion, reaching its maximum in from five to eight hours after food has been taken; the secretion then diminishes, but never entirely ceases, except under pathological conditions.

Increase of pressure in the circulation of the liver is followed by increase of the secretion; whilst lowering of pressure, as in sudden obstruction of the portal vein, is followed by its diminution or suppression. The diabetic puncture in the floor of the fourth ventricle causes diminution of the flow of bile.

Rutherford, Vignal, and Dodds have shown that most purgatives increase the secretion—*e.g.*, aloes, rhubarb, jalap,

colocynth, cream of tartar, sodium sulphate; but this is especially the case with podophyllum, corrosive sublimate, salicylate of soda, iridin, and euonymin. Calomel produces less decided effects; lead diminishes the secretion.

Great variations are met with in the composition of bile. The following, taken from Hoppe-Seyler, is the mean of five analyses of human bile:—

Water	91.68
Inorganic matter }	
Organic matter	8.32
Mucus	1.29
Taurocholate of sodium	0.87
Glycocholate of sodium	3.03
Saponified fat	1.39
Cholesterolin	0.35
Lecithin	0.53
Fat	0.73

The most important constituents of bile are its *pigments and acids*.

The bile pigment is *bilirubin*, derived by oxidation from the pigment of the blood-corpuscles, oxy-hæmoglobin. By further oxidation bilirubin is converted into a series of colouring matters, of which the green pigment, *biliverdin*, is the ultimate stage.

The bile acids are *glycocholic acid* ($C_{26}H_{43}NO_6$) and *taurocholic acid* ($C_{26}H_{45}NSO_7$). They occur in the form of salts of sodium.

The functions of the bile are said to be: (1) To precipitate the soluble peptone—a very doubtful function, as the action of the pancreatic juice, which reaches the intestine at the same time, must be to re-dissolve the peptone; (2) to emulsify and promote the absorption of *fats*, a much more useful property; it is probably on this account that liver oils are more readily digested than ordinary fats; (3) a diastatic action on starch, which is not constant, is often very slight, and can only be observed in the bile of an animal freshly killed.

Nothing is definitely known about the pathological alterations of the bile. Allusion has already been made to the conditions under which its quantity may vary. In passive congestions it is probably diminished, in active hyperæmia increased, while in all diseases which destroy the liver tissues diminution of bile must follow.

In severe vomiting bile is sometimes quite *blue*, but this is merely the result of an oxidation change of the normal pigments.

Albumen has been found in the bile in

Bright's disease, but the meaning of this is not clear (Vulpian, Frerichs).

Leucin and tyrosin may be present in the bile in various diseases without having any very special significance (Anderson).

In acute yellow atrophy the bile may be colourless (Thierfelder).

In dropsy of the gall-bladder the contents may be quite colourless, but this can hardly be called *bile*.

R. SAUNDBY.

BILHARZIA HÆMATOBIA(*Dis-toma Hæmatobium*).—This is a species of trematode worm, which has been proved to be the cause of the hæmaturia that is endemic in Egypt, various parts of Africa, Arabia, Madagascar, Mauritius, and elsewhere. The sexes are distinct, the female being nearly twice as long as the male, but much more slender. The mode of introduction of the parasite is uncertain; probably it enters the body in the drinking water, but some writers are of opinion that it invariably enters through the urethra in bathing. The worm probably resides in the veins in the region of the bladder and prostate. This is, however, doubted by some writers; it has been found elsewhere, notably in the portal veins. The complete life history is still unknown, but there is almost certainly an intermediary host. Ova have been found in the capillaries of the lungs, kidneys, and skin, and are passed by the sufferers from this disease in enormous numbers in the urine. Their presence in and upon the mucous membrane of the bladder gives rise to the formation of inflammatory granulation tissue, and in one reported case was believed to have been the cause of an epithelial cancer.

The prominent *symptom* is hæmaturia, with the result that the patients are usually anæmic. At the beginning of the disorder small quantities of almost pure blood are passed towards the end of micturition, and later on blood-clots of considerable size. There is generally a good deal of pain in the region of the neck of the bladder and in the urethra, especially during micturition; pain in the buttock is also common. The urine is turbid; it often contains crystals of oxalate of lime and shreddy filaments, branched and curling at their ends, with minute white or yellowish opaque specks in their midst. Under the microscope the filaments are seen to be homogeneous fibres, with mucus cells, forming a stroma in which some ova are imbedded. The sediment to the naked

eye consists of—(1) Minute, opaque, roundish masses, white, yellow, or red, (2) brightly blood-stained cylinders, often branched, and (3) flat blood-clots; microscopically, free ova will be found, together with pus and blood-corpuscles and every variety of epithelial debris from the urinary tract. The egg is a bright, translucent body, ovoid in shape, with a minute spike at one end, and is readily seen, even under a low power. The shell is transparent, and the embryo is plainly visible within, being generally adherent at one or more points to the shell; it is completely surrounded by cilia, by means of which it moves with great rapidity when free. Diluting the urine with ten times its bulk of water suffices to hatch the ova, but the embryo speedily dies in undiluted urine. The period of incubation is quite unknown. In a few instances filariæ have been detected in the blood, probably a mere coincidence. The disease may come on at any age, even as early as three years; it is much more common in the male sex. Children who are attacked usually recover by the time they reach maturity; this is not so likely to occur in adults, but the disease often becomes quiescent.

The *treatment* should be directed to the improvement of the general health of the patient rather than to any attempt to kill the worm by internal or local treatment. In countries where the disease is known to be endemic it will be advisable to avoid bathing, and only to drink water which has been boiled and filtered.

JOHN ABERCROMBIE.

BILIOUS is a popular, not a scientific term. A person is said to be bilious when he has vomiting or diarrhoea, or both, the vomit and motions being highly charged with bile, and with these symptoms there will be anorexia, a furred tongue, and a muddy, jaundiced tint of skin. The theory which the name implies, that such a person is suffering from excessive formation of bile, has no foundation in fact. A rigid attention to diet, with perhaps abstinence from food for half a day, would form the most important part of the *treatment*. Salines and alkalies may be administered with advantage.

BRAIN, ABSCESS OF.—Abscess of the brain is nearly always secondary, the idiopathic form being almost unknown. It is more commonly met with in the white matter than in the grey, and its most frequent seats are the centrum

ovale, the temporo-sphenoidal lobes, and the lateral lobes of the cerebellum.

The *causes* of cerebral abscess may be either *local* or *distant*. Inflammation of the bones of the skull resulting from direct injury, such as a blow or fall on the head with fracture, followed perhaps by caries or necrosis; and suppurative disease of the middle ear are by far the most common local causes of abscess. In the latter case there is usually a history of purulent and possibly fetid discharge from the ear of some years' duration, generally with perforation of the tympanic membrane and earies of the temporal bone. But there may be disease of the middle ear without perforation, discharge, or disease of the bone. By some means, imperfectly understood—it may be by the perivascular and lymphatic canals—infection is carried to the brain, and an abscess results, its most common sites being the temporo-sphenoidal lobe and the cerebellum. Disease of the nose and of the ethmoid bone, syphilitic or not, is also a rare cause. Amongst causes operating from a distance are certain diseases of the lungs and pleuræ, especially bronchiectasis, gangrene, and empyema, and also general pyæmia. Cerebral abscess, however, is not, on the whole, a common complication of pyæmia.

Symptoms.—The disease may run an acute course, or the abscess may be present for some months without giving rise to obvious symptoms. When the abscess follows an injury, after a varying period there may be severe headache, localized to the seat of injury, vomiting and pyrexia, with rigors. The temperature, however, in the majority of cases is low, and the pulse slow, a marked contrast to the conditions usually found in meningitis. Optic neuritis is often present, but is less common and less severe than in cases of cerebral tumour. When abscess follows disease of the middle ear and is situated in the temporo-sphenoidal lobe the symptoms are often very obscure. A purulent discharge may have suddenly ceased, and for some days following the patient may have complained of headache, gradually increasing in severity. He then becomes drowsy and stupid, but there is rarely any definite paralysis. If the so-called motor area be involved, convulsions may occur associated with hemiplegia or monoplegia, but sensation is not affected unless the disease involves the posterior part of the internal capsule. There may be delirium, but the mental condition is more

often one of torpor and indifference to surroundings; this passes on to stupor, which deepens into coma, with brown dry tongue and relaxation of sphincters, when, if not relieved, the patient dies.

In the *chronic* form the condition may be latent for a period varying from a few months to several years, symptoms being absent so long as the abscess remains encapsuled, or there may be occasional complaints of headache with irritability of temper, and sometimes convulsions resembling ordinary epilepsy. The latent period ends suddenly or gradually, the change being marked by increased headache, and possibly by the occurrence of rigors. The symptoms now become those of the acute form, already described.

Localization of the Lesion.—The symptoms of abscess in the motor cortex and in the neighbourhood of the temporal bone have already been indicated. Further indications may be obtained by testing the grasping power of the hands with the dynamometer. Abscess in the frontal region may cause no symptoms beyond mental dulness or melancholia. If the speech centre be destroyed, there will be aphasia, but this symptom may also be present in the case of a large abscess in the left temporo-sphenoidal lobe, compressing the third frontal convolution. In the corona radiata, hemiplegia or hemi-anesthesia may be produced by destruction of the motor or sensory fibres, but abscess in the basal ganglia often causes no special symptoms, unless the internal capsule be involved. The cranial nerves are liable to be affected with abscess situate at the base of the brain. The signs of abscess in the lateral lobes of the cerebellum are often very obscure; pain may be referred to the occipital region, but it is an unsafe guide. If the middle lobe be affected, the gait may be staggering.

The *diagnosis* is often difficult, as the disease may vary in duration from a week in the acute form to many months in the chronic variety. In the acute form, when there is a history of injury or fracture, and when this is followed by localized headache, with tenderness, pyrexia, rigors, vomiting, and perhaps local convulsions in the limbs, the diagnosis is comparatively easy; but in the chronic form, where the symptoms are slight or absent, and the terminal symptoms occur suddenly, it may present great difficulties. In any case of long-standing disease of the ear in which sudden cessation of a discharge is fol-

lowed by headache and increasing drowsiness, the presence of a cerebral abscess is highly probable.

The chronic form has mainly to be diagnosed from tumour of the brain. In the latter the symptoms are more slowly progressive, whilst the rapid development of severe cerebral symptoms after slight indications of brain disease have existed for some time is in favour of abscess, especially if accompanied by considerable fever and rigors (Gowers).

Injury points rather to abscess, but it also gives rise to tumour in some cases. As already stated in the diagnosis of abscess from meningitis, the state of the pulse and temperature is of great importance; the two conditions may, however, be combined.

Pathology.—In the first stage the vessels are much distended, and there is an exudation of leucocytes into the tissues around. The nerve elements then undergo degeneration. The leucocytes increase and form an abscess, which may be ill-defined and surrounded by softened brain substance or may present a distinct capsule. This is formed primarily of delicate nervous tissue which may subsequently develop into a thick fibrous envelope. It is in this way that an abscess becomes encapsuled and latent. The capsule may be completely closed, or in a case of fracture of the skull it may communicate by a fistulous canal with a spicula of bone. The contents of the abscess are usually of a greenish colour, and may have a peculiarly fetid odour. Cerebral abscess may be either single or multiple; in the former case it is usually of considerable size, equal to that of a walnut or a hen's egg. Multiple abscesses are generally smaller.

The *prognosis* is always very grave, unless the abscess can be evacuated by surgical operation; in very rare cases it may become firmly encapsuled, but when well-marked symptoms have occurred such a result can hardly be hoped for.

Treatment.—The possibility that the symptoms may subside and the abscess become encapsuled is so remote that it may be disregarded in the consideration of the treatment to be adopted. Generally speaking, a fatal termination is certain unless the contents of the abscess can be evacuated. Recent advances in cerebral surgery have fortunately rendered this step possible, and the number of cases in which an abscess of the brain has been successfully treated by operation is now considerable.

The most probable situation of the

abscess under various circumstances has already been described.

In the case of injuries to the head the skull should be trephined over the seat of the fracture or blow, unless there be definite localizing symptoms, in which case the indications they afford are a safer guide to the seat of disease. If, on exposing the brain, the surface appear healthy, a grooved or hollow needle should be passed into its substance with the hope of striking the abscess. When found, the pus must be evacuated and a drainage-tube inserted.

In a case recently operated upon by Mr. J. B. Sutton at the Middlesex Hospital, an abscess in the temporo-sphenoidal lobe secondary to caries of the temporal bone was first opened by trephining in the usual position for abscess so situated, but the drainage not being free a second trephining operation was performed, and the bone forming the roof of the auditory canal removed. By this means the abscess was struck again at its lowest point, and its contents were discharged through the canal.

It is possible that when the petrous bone is diseased and the dead bone can be felt, this latter operation will prove the most successful, as the abscess, if found, is necessarily opened at its most dependent part, and free drainage is secured through the auditory canal. The carious bone can also be removed at the same time.

If the abscess be in the cerebellum, its most frequent site is opposite the opening of the internal auditory canal. It may be drained by trephining the occipital bone beneath the inferior curved line and passing a trochar and canula forwards and slightly inwards through the substance of the cerebellum.

For the details of the operations here mentioned, works on surgery must be consulted.

C. E. BEEVOR.

BRAIN, FUNCTIONS OF.—A

knowledge of the functions of the different parts of the brain is absolutely essential for the purpose of exact diagnosis in cases of cerebral disease.

The principle of localization of the functions of the brain was first put on a satisfactory basis by the stimulation experiments of Fritsch and Hitzig in Germany and of Ferrier in this country, and the work has been carried on by other physiologists.

It will be advisable to describe the functions of the different parts of the brain under the following headings:—

Cerebral convolutions, corona radiata and internal capsule, and cerebellum.

It will be observed that in the above list no mention is made of the basal ganglia; formerly the corpus striatum was considered to be the motor and the optic thalamus the sensory ganglion, but the functions originally ascribed to these ganglia are really those of the adjacent parts of the internal capsule, and there are no definite symptoms by which a lesion involving the basal ganglia only can be recognized. The account here given refers to the brain of the Macaque monkey, but the close analogy between the brain of the monkey and man, confirmed, as it is, by the data drawn from pathological observations, justifies us in referring the results obtained by experimentation on the one to the other.

1. The cerebral convolutions contain areas for the representation of (a) movements, (b) sensation, and (c) the special senses.

(a) The so-called *motor area* occupies the convolutions about the fissure of Rolando in each hemisphere—viz., the ascending frontal and parietal convolutions on each side of the fissure, the posterior part of the three frontal convolutions, and the parietal lobule, the continuation upwards and backwards of the ascending parietal convolution. In addition to these, there is the contiguous part of the marginal convolution along the mesial surface of the hemisphere.

Stimulation of this region by a weak Faradic current produces movement in various parts of the opposite half of the body.

To indicate clearly the order in which the motor areas for the different parts of the body are situated in the cortex, it will be well to begin at the mesial line, and then to pass outwards and downwards along the fissure of Rolando to the fissure of Sylvius; by so doing we shall find that the functions represented range in order from the least highly evolved to the most highly specialized—i.e., starting with movements of the abdominal muscles, we end with the centre for speech.

Taking first the marginal convolution, Profs. Horsley and Schäfer have shown that movements of the rectus abdominis of the opposite side only, and also movements of rotation of the trunk to the opposite side, are produced by stimulating the middle of the excitable part of the marginal gyrus. In front of this, movements of the arm are obtained, and, behind it, movements of the lower limb.

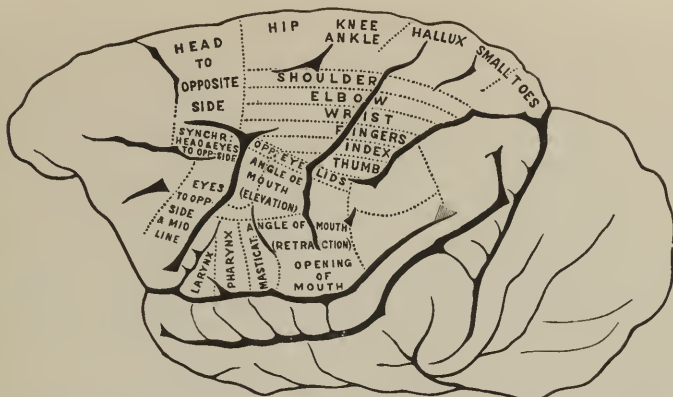

Diagram of the Brain of a Macaque Monkey, showing the areas for the representation of the movements of various parts. (Horsley and Beevor.)

The principal area for the movements of the lower limb is situated in the highest part of the outer surface of the cortex—i.e., the part next to the middle line. This, in the monkey, reaches in front to the vertical level of the præcentral sulcus, and behind to the posterior extremity of the parietal lobule. According to some observations made by the writer, in conjunction with Mr. Horsley, the representation of the different parts of the lower limb can be differentiated (*Phil. Trans. Roy. Soc.*, vol. 179, B, p. 205). The most important of these is the representation of the great toe, which is situated immediately in front and also behind the superior end of the fissure of Rolando—i.e., the end nearest to the middle line. Further, the representation of the hip is in the most anterior part of the area, while that of the smaller toes is behind the fissure of Rolando.

Passing down the fissure of Rolando, we find the area for the representation of the upper limb next to that of the lower limb, occupying the ascending frontal and parietal convolutions as far down as a line drawn across the fissure of Rolando from the lower end of the intra-parietal sulcus to the upper end of the præcentral sulcus. This area corresponds to about the middle two fourths of the fissure of Rolando.

According to Mr. Horsley and the writer, the different segments of the limb are represented in the following order from above downwards—viz., shoulder (nearest to the middle line), elbow, wrist, fingers, index finger, thumb. The thumb can be made to flex alone by stimulation of the cortex in the ascending parietal

convolution just above and in front of the lower end of the intra-parietal sulcus.

Just below the area for the upper limb there is a very narrow strip running across the fissure of Rolando between the præcentral and the intra-parietal sulci, stimulation of which was found by Mr. Horsley and the writer to produce closing of the lids of the opposite eye.

The rest of the ascending frontal and parietal convolutions between the area last described and the fissure of Sylvius is occupied by the areas for the representation of the buccal cavity and the throat.

Thus, in the upper half of this region we have elevation of the angle of the mouth of the opposite side, and below this retraction of the angle of the mouth, and in the part of the cortex next to the fissure of Sylvius we have from behind forwards (1) opening of the mouth around the lower end of the fissure of Rolando; (2) movements of mastication and (3) contraction of the vocal cords, which Semon and Horsley found to be bilaterally represented in the cortex of each side (*Phil. Trans. Roy. Soc.*, vol. 178, B, p. 153). This last area—i.e., for the larynx—brings us close to what is known as the speech centre, situated in man in the posterior part of the left third frontal convolution, destruction of which by hæmorrhage or softening is followed by aphasia.

Besides the areas mentioned above, there is another situated in front of the præcentral sulcus, and occupying the posterior part of the frontal lobe just in front of the ascending frontal convolution. This is for the representa-

tion of the movement of turning the head and eyes to the opposite side, and is the most extensive of all, as it reaches from the median line, above, almost to the fissure of Sylvius, below. Its large extent is perhaps due to the fact that all purposive movements of the limbs are preceded by turning the head and eyes in the direction of the desired movement. The middle of this area—i.e., the part in the hollow of the præcentral sulcus—is for the representation of the simultaneous action of turning the head and eyes to the opposite side, while nearer to the middle line the head tends to move alone, and below, nearer to the fissure of Sylvius, the eyes move without the head.

As already stated, the above account is a description of the results obtained on stimulation of the brain of the Macaque monkey, taking the primary movement—i.e., the first movement obtained on stimulating a given point—as representing the dominant function of the part. By stimulating the excitable cortex of an Orang, Mr. Horsley and the writer obtained results (not yet published) which prove that the primary movements observed in the Macaque correspond very nearly with the single movements obtained in the case of the Orang, these latter being probably very nearly the same as in man.

(b) *The area for the representation of sensory impressions* is considered by Dr. Ferrier to be in the hippocampal convolution, while Profs. Horsley and Schäfer have found that the gyrus fornicatus, which is the continuation of this convolution forwards along the mesial surface, is also part of the area for the representation of anæsthesia. At present, however, no differentiation has been made out for the different parts of the body.

Besides definite anæsthesia, Mr. Horsley has noticed, in cases of lesion of the so-called motor area, a form of perverted sensation, in which an impression is always referred—say, in the hand—to a phalanx higher up than the one touched, and the person complains of subjective numbness, and there is loss or impairment of muscular sense.

(c) *The special senses*, as sight, hearing, taste, and smell, have been localized in the cortex. *Sight* is represented in the occipital lobe, and also in the contiguous angular gyrus in the parietal lobe. In the occipital region the corresponding half of each retina is represented, so that with a lesion of the left occipital lobe

the left half of each retina would be affected, and consequently the person would be unable to see objects to the right of the middle line—i.e., he would have right hemianopsia. In the angular gyrus Dr. Ferrier considers that the whole field of the opposite eye is represented, and also to a less degree the whole field of the eye of the same side; so that from a lesion of the left angular gyrus there follows extreme concentric diminution of the field of vision of the right eye, and a slight diminution of the left field; this is called "crossed amblyopia."

Hearing has been localized in the first temporo-sphenoidal convolution by Dr. Ferrier, but this has been contested by Mr. Schäfer, so that the question is still *sub judice*.

Smell.—From experiments by Dr. Ferrier, and from the facts of comparative anatomy, this sense has been localized in the inner surface of the tip of the temporo-sphenoidal lobe, but, unlike the other special senses, the olfactory centre receives impressions from the nostril of the same side, not the opposite. Some clinical cases have been recorded bearing out the truth of the above localization. (See a case of epilepsy with olfactory aura, *Med. Soc. Proc.*, vol. xii., by Dr. Hughlings Jackson and the writer.)

The centre for *taste* has not been differentiated from that of smell.

The part of the cortex which is in front of the excitable, so-called motor area, and which lies between this and the anterior extremity of the frontal lobe, is considered to have no motor function, but is thought to be the seat of the highest mental processes. Lesions in this part do not produce paralysis, but symptoms of mental dulness or melancholia.

2. *The corona radiata and internal capsule* are made up of the fibres which pass down from the cortex to form the pyramidal tract in the pons and medulla. How many of these fibres end in the basal ganglia (corpus striatum and optic thalamus) is not known, but it is certain that a large number of the fibres pass directly from the so-called motor cortex to the pyramidal tract without any connection with the basal ganglia.

The internal capsule consists of an anterior and posterior limb joined at an angle. The anterior limb is for the most part inexcitable, but the greater part of the posterior limb (commonly described as the anterior two-thirds, but on the average it is more than this) is excitable, the fibres being arranged in the following

order. Beginning in front we have—(1) opening of the eyes; (2) turning of the eyes to the opposite side; (3) turning of the head to the opposite side; (4) opening of the mouth; (5) movements of the tongue; (6) elevation of the opposite angle of the mouth; (7) movements of the upper limb; (8) movements of the rectus abdominis and other trunk muscles of the opposite side; and (9) movements of the lower limb. (For detailed account, see paper in *Phil. Trans. Roy. Soc.* by Mr. Horsley and the writer.)

The fibres of the extreme posterior part, commonly called the posterior third of the hinder limb of the internal capsule, are considered to be sensory, and a lesion there produces not only hemi-anæsthesia of the opposite half of the body, but also affects the opposite special senses as well.

The exact functions of the different fibres of the *corona radiata* have not been accurately worked out—in fact, it is almost impossible to do so by stimulation—but they are probably intermediate between the positions for the representation in the cortex and in the internal capsule. The great point of difference between the symptoms resulting from lesions, such as tumours, in the cortex and in the corona radiata is that local convulsions are not produced unless the cortex itself be involved, whilst lesions of the corona radiata are characterized by a slowly progressive hemiplegia. The hemiplegia which results from similar lesions in the cortex is of yet slower development.

Cerebellum.—Lesions of the anterior part of the middle lobe produce in certain animals, according to Ferrier, a tendency to fall forwards in walking, whilst injuries to the posterior part of this lobe cause the animal to fall backwards. When the lateral lobe is injured or its middle peduncle divided, the animal has persistent movements of spinning round on its vertical axis, the movement occurring in a direction which, in the case of man, with division of the left middle peduncle, would produce rotation on the vertical axis from left to right. If the lesion of the left lateral lobe and left middle peduncle be slight, the animal falls towards the opposite side—i.e., the right. On the other hand, according to Nothnagel, with whom Gowers agrees, there are no symptoms of loss of equilibrium produced by lesion of the hemispheres unless the middle lobe be involved, and, according to the same observers a lesion of the lateral lobes

alone does not produce loss of function of the cerebellum. Lesions of the cerebellum do not in themselves cause any paralysis unless pressure be exerted on the pyramidal tracts in the pons or medulla. Tetanic fits with opisthotonos have been described especially by Dr. Hughlings Jackson, but it is uncertain whether they result from disordered function of the cerebellum or from pressure on the pyramidal tract.

C. E. BEEVOR.

BRAIN, TUMOURS OF THE (Cerebral Tumours).—The symptoms resulting from the presence of a tumour within the cranium may be divided into general, and special or localizing.

The general symptoms are three—viz., headache, double optic neuritis, and vomiting. They serve to indicate that there is an intra-cranial growth, but give no clue to its exact position.

Headache is usually very severe and continuous; it may be either general or, if the disease be situated upon the surface of the brain, localized to one spot, in which case there may also be some tenderness on percussion.

Double optic neuritis may occur without impairment of vision (Hughlings Jackson), and is probably due either to extension of tissue irritation along the optic tract or to meningitis. The rapidity with which the neuritis passes into atrophy is an indication of the progress of the growth.

Vomiting often occurs daily; it is not preceded by nausea, and is of purposeless character, being without relation to the condition of the stomach. This symptom is most frequently present with growths situated in the medulla and cerebellum.

The special symptoms are those which enable us to localize the growth more exactly.

Tumours in the so-called *motor area of the cortex*, grouped around the fissure of Rolando and in the membranes overlying these parts, give rise to localized Jacksonian fits (epileptiform seizures), which begin with tonic spasm of the parts affected by the growth—i.e., with movements of the face, arm, or leg, or with turning of the head and eyes to one side. There may be considerable intervals between the course of the fits, or several may occur in a single day. They are usually unattended by loss of consciousness, and may be followed by paralysis of the part of the body convulsed.

Growths in the *prefrontal region* in front of the motor area do not cause paralysis

directly; they may give rise to general epileptic fits, and are attended by mental symptoms, such as melancholia and failure of mental powers.

Hemianopsia is a symptom of tumours situated in one *occipital lobe*, whether involving the grey matter or the central white fibres. If the lesion be of the *left lobe*, the patient is unable to see objects to the *right* of the middle line, and *vice versa*. Tumours in the *central white matter* of the hemisphere below, but not involving the motor cortex are characterized by a slow hemiplegia lasting over several weeks, but without Jacksonian fits. The paralysis is due to the fibres of the corona radiata being progressively involved, but there is no anæsthesia unless the growth extend backwards behind the motor area.

Lesions of the *internal capsule and basal ganglia* are difficult to distinguish from disease of the corona radiata, as they have many points in common. The group of symptoms which would lead one to diagnose a growth involving the internal capsule is a hemiplegia rapidly affecting the different parts of the body, with hemi-anæsthesia and hemiopia. The latter symptoms are more likely to occur than when the lesion is in the centrum ovale, owing to the hinder part of the internal capsule being involved.

Tumours growing at the *base of the brain* are usually accompanied by paralysis of one or more of the cranial nerves. If situated in the *anterior fossa*, the optic nerve or its chiasma may be involved, producing unilateral loss of sight or temporal hemianopsia. If in the *middle fossa*, the fifth nerve is especially likely to be affected; whilst tumours in the *posterior fossa* often involve the sixth nerve, causing paralysis of the external rectus only, or the facial and auditory nerves. When there is pressure on the spinal accessory and hypoglossal nerves, half of the tongue and palate, and the vocal chord of the same side, are paralysed.

Growths in the *crura cerebri* produce hemiplegia of the opposite side, with paralysis of the third nerve on the same side; and tumours in the *substance of one half of the medulla and pons* cause complete facial paralysis of the same side, conjugate deviation of the eyes to the opposite side (owing to the nucleus of the sixth nerve being affected), and hemiplegia of the opposite side.

In tumours of the *cerebellum*, involving the middle lobe, a characteristic symptom is a reeling gait, and in some cases

nystagmus. Paralysis of the limbs is produced if there be pressure on the pyramidal tracts; tetanoid convulsions are also met with in cerebellar tumours.

The *diagnosis* has to be made from meningitis, hysteria, albuminuria with uræmia, and from lead poisoning; but by a careful consideration of the symptoms given above a diagnosis can usually be made.

The *prognosis* as a rule is exceedingly grave, the most favourable cases being those in which the tumour is either tubercular or syphilitic, as such growths sometimes become arrested. The latter are most amenable to treatment. The recent progress of cerebral surgery has rendered the prognosis more favourable than formerly. The duration of life in cases in which the tumour, either, is not, or cannot be, removed by operation varies from six months to two years (Gowers).

Ætiology.—With regard to *sex*, tumours of the brain are met with twice as often in males as in females, and are more common in childhood and young adult life than in advanced age.

Character.—According to an analysis of cases collected by Ladame and Bernhardt (quoted by Gowers), the tubercular variety is the most common; then come the gliomata and sarcomata; but in the fifty-four cases recently shown at the Pathological Society, sarcomata were the most numerous, gliomata and tubercular growths standing second and third in order of frequency. In addition to the above, psammomata, gummata, carcinomata, fibroids, simple and hydatid cysts, and cysticercus are also met with.

Situation.—The most frequent sites of tumours are as follows, arranged in order of frequency:—Cortex cerebri and subjacent white matter, pons and crura, cerebellum, basal ganglia and ventricles, cerebral envelopes, cranial nerves.

Of the different forms of tumour it may be said that the *tubercular* grow in the lymphatic sheaths, and are most frequent in the cortex.

Gliomata occur in the cerebral and cerebellar hemispheres; less often in the basal ganglia and pons.

Syphilomata grow from the pia mater along the peri-vascular sheaths, and are met with in the cerebral cortex and pons.

Sarcomata grow from the membranes, from bone, or in the brain substance, and very frequently also in the basal ganglia.

Carcinomata are more commonly met with in the basal ganglia.

Parasitic growths occur in the white substance or in the ventricles of the cerebrum.

Gliomata and carcinomata are infiltrating, tubercular and syphilitic growths, and the sarcomata are not.

Gliomata are single, while tubercular and syphilitic tumours and sarcomata are often multiple.

Treatment.—In tubercular cases tonics and cod-liver oil are indicated, whilst in syphilitic cases a course of mercury and iodide of potassium should be thoroughly carried out. Where a diagnosis can be made of cortical, or even sub-cortical, growths, a surgical operation should be advised. Owing to the labours of McEwen and Horsley, the removal of cerebral tumours has been brought within the domain of surgery, and many successful cases have been recorded. After a course of treatment has proved unavailing, an operation should certainly be recommended if the growth can be localized; and even in the case of tumours deeply seated in the cerebrum or cerebellum it is sometimes advisable to make an opening in the skull to relieve the pressure and the agonizing headache, even if the growth cannot be removed. Morphine, Indian hemp, chloral, and ice to the head are the chief remedies for relieving pain.

C. E. BEEVOR.

BRIGHT'S DISEASE.—The term Bright's Disease includes several different organic affections of the kidneys, which in this article are classified thus:—

- | | |
|---------|---|
| Acute | Acute parenchymatous nephritis. |
| Chronic | Chronic parenchymatous nephritis. |
| | Granular contraction of the kidneys. |
| | Albuminoid degeneration of the kidneys. |

The descriptions of these diseases follow in the above order.

Acute Bright's Disease (Acute Parenchymatous Nephritis).—*Symptoms.*—The affection generally begins suddenly with chilliness or rigors, vomiting, headache, and pain in the back; soon the temperature rises slightly, and œdema appears in the face and other parts of the body. When occurring as a sequel of scarlet fever, the symptoms are more insidious in their onset, and the first sign of the renal affection may be swelling of the face coming on about the

third week after the commencement of the primary fever.

When the symptoms of the nephritis are fully developed, the *skin* is dry and pale, the subcutaneous tissues are swollen and œdematous in all parts of the body, but the change is most apparent in the face. A characteristic appearance is produced by the pale and swollen eyelids and cheeks. The *pulse* is increased in frequency, and is of markedly high tension.

The *urine* is voided frequently, but is scanty in quantity, and may, indeed, be for a time entirely suppressed. It is of a dark smoky hue, and gives a copious brownish deposit on standing. Its specific gravity is increased in inverse proportion to the quantity passed. The reaction is usually acid. The urine invariably contains a large amount of albumen. Blood can in almost all cases be detected by the guaiacum-ether test. In nearly all cases red corpuscles may also be found when the urine is examined under the microscope. A condition has, however, been observed in which only the blood-colouring matter was present (hæmoglobinuria); this replaces for a time a true hæmaturia. The urinary deposit consists of casts of the renal tubes; epithelium from the kidney, renal pelvis, and the bladder, with the free nuclei of the epithelial cells. Blood-corpuscles of both varieties, and a granular organic débris mixed with a quantity of amorphous urates, are also present. The tubercasts vary in size, and consist usually of the hyaline, epithelial, and blood varieties. Occasionally granular casts may also be seen. The epithelial cells and blood-corpuscles undergo considerable alterations from their prolonged soaking in the urine, becoming at last broken up and disintegrated. The quantity of urea excreted daily is always diminished, and the total amount of the natural solid constituents of the urine is generally lessened. The patient complains of heaviness and an aching pain in the loins, and tenderness is experienced when pressure is applied over the lumbar region either in front or behind. Sometimes also a fullness can be felt here due to enlargement of the kidney.

The *heart* may, at an early period, show some enlargement from dilatation of its cavities, and, even before the acute symptoms have entirely passed away, may, in rare cases, give some signs of true hypertrophy. A blowing systolic murmur at the apex of the heart may accompany dilatation of the ventricles.

As the disease progresses, the *blood* becomes poorer in quality and loaded with matters which ought to be eliminated by the kidneys. The mucous membranes, as well as the general surface of the body, therefore become anæmic. Respiration is hurried, and, at the bases of the lungs, some impairment of percussion resonance, with bubbling and crackling râles indicate congestion and œdema of these organs. The pleuræ and peritoneum may give signs of a moderate amount of serous effusion. The temperature is somewhat raised, but presents no typical curve. The tongue is dry and coated, the bowels confined, the appetite is lost, and there is great thirst.

Such are the ordinary symptoms of the disorder. They are prone to present themselves in diverse combinations, now one symptom, and now another, being the most prominent. The anasarca especially varies in its situation and amount from time to time. The predominance of the dropsy in certain parts occasionally gives rise to alarming symptoms. The lungs may be waterlogged by œdema: the pleuræ and peritoneum may be so filled with serous fluid that dangerous pressure is exerted upon the surrounding organs; the legs may be excessively swollen, may inflame, and even become gangrenous; the loose tissue about the glottis may swell from œdema and threaten asphyxia. Further dangers impend from the gradual accumulation of excrementitious matters in the blood by reason of the inaction of the kidneys. Convulsions, coma, severe headache, and vomiting may be thus produced, and constitute very serious complications. They will be more fully discussed in the article on URÆMIA. Inflammation of the lungs and of the pleuræ, pericardium, and peritoneum are prone to arise. Certain eye phenomena are met with. Frequently the retina is lazy, apparently from œdema; flame-shaped hæmorrhages are not uncommon, and occasionally signs of inflammation of the optic papilla are apparent.

That form of the disorder in which the glomeruli of the kidney are specially affected (glomerulo-nephritis: *see below*) is characterized by the presence of excessive dropsy and by the early occurrence of uræmic phenomena.

Course.—The disease may end in recovery or in death, or may lapse into chronic Bright's disease.

The course towards recovery is inaugurated by a decline of the pyrexia, a much freer discharge of urine and a

diminution of the amount of blood therein contained. The urine becomes of lower specific gravity; the albumen and tube-casts diminish in amount and finally disappear, the small hyaline casts being the most persistent. The œdema of various parts is gradually removed, the dryness of skin becomes less apparent, the pulse resumes its normal tension, and, after a period of more or less protracted convalescence, not infrequently interrupted by one or more recrudescences of the disorder, the normal state is attained.

Death may be caused by any of the untoward conditions mentioned above. Further, cardiac failure is frequent, for the heart may not have sufficient reserve power to overcome the increased arterial tension. In such a case the pulse assumes the characters of "virtual tension" (*see PULSE*), and the feeble heart dilates to a dangerous extent. Finally, the albumen may never entirely disappear from the urine, the dropsy of the integuments and internal parts may remain in diminished amount, the pulse may retain its characters of high tension, and gradually the case assumes the appearance of one or other of the forms of chronic Bright's disease.

Diagnosis.—The recognition of the disease is nearly always easy; it may, however, be difficult to determine whether an acute attack is merely a complication of the chronic disease, as is very often the case, or whether it has been primary in its onset. The absence of similar symptoms at any preceding time, of any hypertrophy of the heart at an early stage of the affection, of fatty elements in the urinary deposit, and of the white patches in the retina, generally called albuminuric retinitis, are all in favour of the disease being primarily acute. If, in addition to the above negative signs, the affection occur in a young person, or after a drinking bout, or as a sequel to one of the specific fevers, the probability that the attack is primary is much increased.

Morbid Anatomy and Pathology.—The organic lesion in this disorder is always an acute inflammation of the kidneys. The kidneys are enlarged, and, on section, the cortex is seen to be disproportionately increased in extent. The medullary portion is of a bright-red colour, showing a longitudinal striation of deep-red lines, some of which are prolonged into the cortex from the bases of the pyramids. The cortex is either red or yellowish-white in colour, or shows a mottling of the two colours. On the cut surface

of the red kidney the Malpighian bodies are seen as red points, and spots of hæmorrhage are here and there apparent, while a bloody fluid exudes abundantly. In the pale kidney the glomeruli are not so easily seen, and may be entirely invisible to the naked eye. In the cases to be described below of glomerulonephritis, the glomeruli often appear as white glistening points on the generally pale surface. In all cases the capsule of the kidney peels off easily, and leaves on removal a smooth surface, on which the congested stellate veins are more than usually prominent.

On *microscopic examination* the changes are chiefly found in the cortical portion of the kidney, and especially in the convoluted tubes, although all parts of the organ are more or less affected. The convoluted tubes are greatly increased in diameter, their cells are swollen, and so amalgamated as to present an almost continuous mass of protoplasm, not easily separated into its cellular elements even at the free margin. The bodies of the cells are no longer striated, but are very granular, and contain large hyaline globules, and sometimes droplets of fat. The nuclei of the cells may be entirely hidden by the swollen protoplasm, and, when seen, are often greatly increased in number. In severe cases the cells exhibit the changes of the so-called "coagulative necrosis." The lumen of the tubule may be entirely obliterated by the swollen epithelial cells; or, again, it may be occupied by a quantity of granular débris, mixed with detached cells, leucocytes, hyaline globules, red blood-corpuscles, and a fibrinous exudation which in the lower tubes forms casts of the lumen. In the later stages, the protoplasm of the cells breaks up into a mass of granules and fat drops, and is to a great extent carried away along the tube. The blood-vessels are engorged, and in the very acute stages numerous hæmorrhages may be seen in and around the tubules.

The colour of the kidney depends upon the relative preponderance of the congestion or of the epithelial change, the enlarged blood-vessels giving the red colour, which is afterwards hidden by the proliferated and swollen epithelial cells. Between the tubules, and especially around the glomeruli, numbers of leucocytes may be seen, but this interstitial infiltration is rarely a marked feature of the disorder. The glomeruli show extreme congestion, and there is often a hæmorrhagic exudation into the interior of Bowman's

capsule, while the small afferent and efferent arteries are occasionally seen to have undergone hyaline degeneration.

In certain cases the glomeruli are the seat of more pronounced changes, to which condition the term "**glomerulonephritis**" has been given. The changes observed are various, and may briefly be described as follows:—There may be proliferation of the cells lining Bowman's capsule (capsular epithelium), or of the cells covering the glomerular tuft (glomerular epithelium), or of the few connective-tissue cells which bind the glomerular loops together. Also there have been observed proliferation of the nuclei of the small capillary vessels of the tuft, and thrombosis of these vessels; while, again, leucocytes, which had clearly exuded from the vessels, have been found between the loops and in the cavity of the capsule. The result of these changes is that the circulation of blood through the glomerulus is greatly interfered with, and consequently its functional activity hindered. Probably the glomerular inflammation is never found without changes in the renal tubes. Of late a few workers have attempted, but unsuccessfully, to show that a glomerular change invariably precedes that of the tubules. Finally, it must be stated that, in certain cases, collections of micrococci have been found in the vessels of the kidney and in and between the tubules.

Ætiology.—Acute Bright's disease is most frequently caused by exposure to cold. It is a common complication of some of the specific fevers, especially scarlet fever, and more rarely of measles, erysipelas, and small-pox. It may also be produced by an overdose of turpentine or cantharides. An alcoholic debauch is not infrequently followed by an attack of acute nephritis. The existence of chronic Bright's disease, or of puerperal albuminuria, or, in the opinion of the writer, of so-called functional albuminuria acts as a predisposing cause for an attack of the acute disorder. In such conditions any of the causes above named, but especially exposure to cold, is the more liable to produce an attack of acute nephritis.

Prognosis.—The prognosis is not so favourable in the young as in those advanced in life. The symptoms of evil augury have been mostly detailed above in describing the complications. The presence of any of these greatly increase the danger of the patient. The condition of the circulatory system is of

great importance. The presence of a considerable degree of dilatation of the heart, indicating failure of the heart-muscle to overcome the increased arterial tension, is a most serious condition. On the other hand, an even more unfavourable sign is the entire absence of an increased tension in the pulse throughout the attack, a condition which sometimes occurs in weakly subjects. The persistence of albuminuria or of anasarca when the other acute symptoms have disappeared is indicative of a probable lapse into the elhronic condition. Nevertheless, a patient may entirely recover after a long convalescence, and when repeated recrudescences of the disease have occurred.

Treatment.—Dr. Mahomed showed that an attack of acute nephritis during the course of recovery from scarlet fever may be averted by proper treatment. High arterial tension and the presence of a small amount of blood-colouring matter in the urine precede the appearance of albumen, and are in turn caused by constipation. A free purgation will remove both these conditions and prevent the onset of renal changes.

At the commencement of an attack of acute Bright's disease the patient should be placed in bed and wrapped in blankets. A hot poultice should be applied to the loins, and renewed as often as it becomes cooled. Dry cupping to the loins is also of value, but it is not advisable to apply the scarificator unless the patient be of a robust frame. The food must be entirely fluid, and contain as little nitrogenous matter as possible. Milk, beef-tea, chicken-broth, barley-water, arrowroot, and such-like articles should form the staple of the dietary. Diluents, such as lemonade, should be given freely, and distilled water (best in the effervescent form, as Salutaris water) should be taken in large quantities in order to wash out the accumulated epithelial debris from the kidneys.

As internal remedies the citrate and acetate of potassium in dilute solution and the liquor ammonii acetatis with a little tinct. hyoscyam. are of great use in allaying the febrile symptoms and promoting the action of the skin. For the same purpose the tartrate of antimony may be given in the form of the wine or the powder, but the alkaline remedies are preferable in all but very robust patients. A hot-air or vapour bath, or the "blanket bath," should be employed every evening. The bowels must be kept freely open by a purge every day or other day.

For this purpose the saline purges and the compound jalap powder are the most advisable.

It is considered dangerous to use mercurial purges on account of the ease with which such patients are salivated. Nevertheless, no drug is so efficacious as calomel in reducing high arterial tension, and the writer does not fear to use it even in acute Bright's disease when the pulse indicates the existence of an excessively high tension. At the commencement of the case 2 grains of calomel with 2 grains of extract of colocynth may be prescribed, followed in a few hours by a saline purge. The further purgation should then be kept up by other remedies, using the calomel again only when the arterial tension becomes excessively high.

Vomiting is best relieved by the sucking of ice, by effervescent drinks, or, if severe, by creosote or carbolic acid internally. Blood-letting is of value when uræmic symptoms present themselves, but for further details the article on URÆMIA may be consulted.

As the more acute symptoms subside, iron preparations should be cautiously given. The tinct. ferri acetatis combined with pot. acetatis is a preparation easily borne, and the alkalies can be stopped as the renal secretion becomes again established and no ill effects are observed from the use of the iron. Dropsy may be combated by (in addition to the remedies already mentioned) digitalis and scoparium. Secondary inflammation of the lungs or of the serous membranes should be treated by mustard poultices and other hot applications, but turpentine and cantharides are to be avoided on account of their irritant action on the kidneys when absorbed. Cardiac dilatation calls for cardiac tonics, such as digitalis, strophanthus, and strychnine; and the dangerous condition mentioned above where the pulse tension is throughout low is best combated by the free use of dilute nitro-hydrochloric acid and strychnine and the early administration of iron.

Chronic Bright's Disease.—Under this heading are commonly grouped three chronic diseases of the kidneys—chronic parenchymatous nephritis, granular contraction of the kidneys, and albuminoid degeneration of the kidneys.

Chronic parenchymatous nephritis is also known as chronic tubal and chronic desquamative nephritis, and the kidney resulting from the discase is often called the large white kidney.

Granular contraction of the kidneys is also known as chronic interstitial nephritis and its result spoken of variously as the small red granular kidney, the red contracted kidney, and sometimes as the gouty kidney or the arterio-sclerotic kidney.

Albuminoid degeneration of the kidneys is also known as the amyloid, waxy, or lardaceous kidney.

Although the division of chronic Bright's disease into three varieties is convenient for purposes of description, yet it must be mentioned that rarely is a case met with in which the changes peculiar to one variety are present alone. Mixed forms are common, and even the rule. In the large white kidney the interstitial tissue is very frequently thickened, in the small red kidney the cells are often in a state resembling that found in parenchymatous nephritis, whilst in amyloid degeneration the kidney is often puckered by the excess of contracting fibrous tissue.

The symptoms and diagnosis of the various forms will be described together, and the morbid anatomy and pathology of each variety will then be treated separately.

SYMPTOMS.—Chronic Bright's disease is sometimes the consequence of an attack of acute nephritis, and the mode of progression from the acute to the chronic condition has already been described. In the majority of cases, however, the onset of the disease is gradual and insidious, and it is not detected until it has been in existence for some time. Sometimes attention is called to the state of the patient by the supervention of symptoms of acute Bright's disease, when it is discovered, on careful inquiry and observation, that the chronic disorder has been previously in existence. Often a little puffiness of the eyelids or of the ankles, breathlessness, dull, throbbing, and persistent headache, disorders of vision, or hebetude and disinclination for customary mental exercises are the first symptoms which cause a suspicion in the mind of the physician that the kidneys are at fault.

The symptoms vary greatly in their grouping and individual intensity according to the form of the disease from which the patient suffers. They may thus be summarized in a general form:—Albuminous urine, depositing tube-casts and renal debris; a pulse of high arterial tension, and hypertrophy of the heart most marked in the left ventricle; frequent micturition, especially at night;

dropsy in various parts of the body; progressive anæmia; dryness of skin; derangements of digestion, and a tendency to the occurrence of uræmic phenomena and of secondary inflammations of the lungs and serous membranes. Some of these symptoms require more detailed description.

Urine.—With the large white kidney, when uncomplicated, the urine is always scanty; with the small red granular kidney it is abundant, except in the later stages, when it becomes diminished in quantity; with the amyloid kidney also it is abundant, and this is often the first sign of the supervention of the kidney mischief upon the chronic wasting or suppurative disease which gives rise to it. Partial suppression of urine for a short time is in any of these forms followed by a discharge more copious even than was the previous habit.

The specific gravity of the urine varies inversely as its quantity. It is therefore low in urine from the granular and amyloid kidneys, high in that from the large white kidney. Nevertheless, it may happen that a urine of low specific gravity is small in quantity; this is, naturally, a condition of ill omen. The colour of the urine is generally somewhat lighter than normal. It may be quite clear, or may deposit on standing a cloud composed of crystals, casts, and renal debris. Occasionally it may contain blood, usually only in very small quantity.

The urine always contains albumen at some period of the disease. In the large white and amyloid kidneys the amount of albumen passed is very large. The urine from the granular kidney, until the very late stages, rarely contains a large quantity of albumen. It may, indeed, for long periods not contain albumen in quantity sufficient to be detected by the ordinary methods. It is to be noted that the albuminuria is influenced by the normal physiological processes, is more pronounced after meals and after exercise, and, moreover, is prone to be more marked in the forenoon than at other times. In doubtful cases, therefore, it is desirable to examine the urine passed shortly after breakfast and exercise, and not to pronounce upon the absence of albumen until several consecutive specimens have been tested.

In the granular kidney a temporary failure of the heart power, which is not an unusual phenomenon, will cause a considerable increase of the albuminuria, lasting only until the heart again recovers strength. In the later stages the

albumen is, even in the case of the granular kidney, abundant, from a combination of weak circulatory power and degenerative changes in the epithelial structures of the kidney.

The reaction of the urine is generally acid, but it may vary. In the deposit from the urine are found casts of the renal tubes, renal epithelium, granular and fatty matter, and occasionally crystals of uric acid and oxalate of lime. The tube-casts are most plentiful in the large white kidney, but are never so numerous as in the acute forms of nephritis. Epithelial and blood casts are rarely met with in chronic Bright's disease. The prevailing casts are the granular, fatty, and hyaline, the last form being often the only one met with in the urine from the albuminoid kidney. The renal epithelium found in the urine may show extreme degenerative changes.

The excretion of the solids of the urine is diminished. The urea, it is to be specially noted, is excreted in greatly diminished quantity.

Intercurrent pyrexia impresses its own peculiar characters upon the urine. Whatever may have been its previous condition, during the pyrexia the urine becomes scanty, of high colour, and more albuminous; it deposits urates on standing, and the excretion of urea is increased.

Circulatory System.—The characteristic pulse of chronic Bright's disease is one of high arterial tension, the features of which will be found described in the article on PULSE. The tension is highest in cases of the granular kidney, is well marked in cases of large white kidney, but when there is pure albuminoid degeneration of the kidney the arterial tension is low. The latter condition is, however, rarely met with. As already mentioned, the albuminoid kidney is most frequently combined with the granular degeneration, and this combination affects the character of the pulse, which is rendered of higher tension than it would otherwise be. In the course of chronic Bright's disease the heart is prone to become weak, sometimes for a short period only, sometimes as the precursor of the end. Under such conditions the pulse becomes one of "virtual tension" (see PULSE), indicating peripheral resistance in the circulation, not overcome by the cardiac systole.

In chronic Bright's disease the heart is enlarged proportionately to the increase of the arterial tension. Thus the enlargement is greatest, and present with

the greatest frequency, in the granular kidney; is least, and is often absent, in the albuminoid kidney. Primarily, at least, this enlargement takes the form of hypertrophy, affecting more especially the left ventricle. The special signs in this condition are, displacement of the cardiac apex downwards and to the left, extension of the deep cardiac dulness in the same direction, a heaving impulse, and a loud, prolonged and booming first sound. At the same time the coincident high arterial tension causes a reduplication of the first sound at the apex, and an accentuation of the second sound at the aortic cartilage. In the later stages, and more frequently in association with the large white kidney than with other forms, the hypertrophy of the heart becomes combined with dilatation of its cavities, the heart muscle becoming weakened, and giving way before the peripheric resistance. The apex impulse is then found to be more diffused and less forcible, the first sound short and sharp, and not infrequently accompanied or followed by a blowing systolic murmur. The existence of chronic Bright's disease furthers the production of atheroma in the arteries and of analogous changes in the valves of the heart. This may give rise to valvular incompetence varying in its symptoms and signs with the valve affected. There is another association of kidney mischief with heart disease, which must not be overlooked, although it does not properly belong to this section—viz., the hardening of the kidney from chronic congestion, secondary to a lesion of the heart. The signs of the kidney mischief in such a case are generally but slight, and occur some time after the cardiac phenomena have been evident.

In the course of chronic Bright's disease the blood undergoes progressive changes. The clinical evidences of these are anæmia of the skin and mucous membranes, dropsical effusions in different parts, and various symptoms which may arise from the action of the impure blood on the nervous system. The actual changes in the blood consist of a diminution in number of the red corpuscles, and an increase of the water, together with a decrease of the amount of albumen, and the accumulation in the blood of urea, uric acid, and extractive matters.

The exact relation between hypertrophy of the heart and kidney disease has been greatly discussed, and diverse views are still held. They can only be briefly summarized here. Bright believed

that the blood, altered in quality by reason of the disease of the kidneys, acted as an irritant to the muscular tissue of the heart, stimulating it to increased work and consequent hypertrophy. But he also suggested that the impure blood did not circulate easily through the capillaries, and that the resistance to its passage called forth the exercise of greater force on the part of the heart, requiring in turn an increase in the amount of muscular fibre. The view that a resistance to the circulation is situated in the capillaries, and that this causes increased arterial tension and so gives rise to hypertrophy of the heart has been supported in more recent years by Dr. Galabin and Dr. Broadbent. After some hesitation the writer is now of opinion that this explanation is most in accordance with the clinical and pathological facts. It has been mentioned above that the blood-flow through the granular kidney is obstructed, and Traube based his view of the relationship under discussion upon this fact. The obstruction causes a diminished quantity of blood to flow through the kidneys in a given time, and consequently the remainder of the arterial system is distended. Moreover, a less quantity of fluid is withdrawn from the blood in the form of the watery constituents of the urine. Both these factors, said Traube, combine to increase the general arterial tension, and so cause hypertrophy of the heart. Bamberger, again, adopted the latter portion of Traube's view. Dr. George Johnson showed that the muscular coat of the arteries throughout the body was hypertrophied. This, he believes, is due to a resistance offered by them to the passage of impure blood to the tissues—a "stop-cock action." The resistance increases the arterial tension, which in turn calls forth the cardiac hypertrophy. Sir Wm. Gull and Dr. Sutton described a further change widely spread throughout the arterial system. This is a deposit of a "hyalin-fibroid" material in the adventitia of the vessels. They believe this to be a primary lesion. It may begin in the kidneys, when it produces the lesions of the so-called "granular kidney," but it may also commence in other parts. The presence of the hyalin-fibroid material in the vessel hinders the flow of blood, increases the arterial tension, and so causes the hypertrophy of the heart. These are the main opinions which have been put forth; there are also numerous minor ones, but it would be inconsistent with the nature

of this work to discuss the matter further.

Cutaneous System.—The skin is dry and harsh, and rarely perspires. It is pale in cases of the large white and amyloid kidneys, sallow in those of the granular kidney. Dropsy of the integuments is very variable in its appearance. In the granular kidney it is the least marked, and may be entirely absent from first to last. In the large white kidney it is most constant, and is often extreme in amount. It is variable also in its duration and seat. It may be widely diffused over the whole body, or limited to the eyelids, the front of the tibiae, and the ankles, or to the genitals. A most characteristic localization of renal dropsy is in the loose tissues immediately below the eyelids, and yet œdema is just as commonly found near the ankles, or on the dorsum of the foot, the seats of election for early cardiac dropsy. Many such cases are really of cardiac origin, and due to the failure of nutrition of the heart fibres.

Eruptions may be met with on the skin. The chief of these are eczematous and erysipelatous inflammations, purpuric spots, and pemphigus.

The **digestive organs** are prone to be disordered. The appetite is poor, and various dyspeptic troubles are complained of. The bowels are, as a rule, constipated, the liver may be somewhat enlarged, and, when dropsy is well marked in other parts of the body, ascites is also present.

Cough and bronchitis are of common occurrence.

The **retina** shows a variety of changes. The most marked lesions are flame-shaped hæmorrhages, and white glistening spots, most numerous near the macula lutea, frequently arranged in lines like the radiations from a star. The latter constitute a most characteristic appearance, from which alone the nature of the disease may be diagnosed. The following changes are also met with:—Optic papillitis, general diffused retinitis, œdema of the retina, and atrophic spots, the remains of old hæmorrhages.

The **nervous symptoms** of Bright's disease are mostly of uremic nature and will be briefly reviewed below. It may be mentioned here that, of late, attention has been called to numbness and pallor of the fingers (*doigt mort*), as an early sign of Bright's disease. The writer doubts if this sign is of any value. Pains of different kinds are frequently complained of. Pain in the lumbar region is

clearly associated with the more deeply situated disease of the kidneys, and tenderness on pressure in the same part is often observed. But neuralgic pains also, affecting the region of distribution of the sciatic nerve as well as other parts, are sometimes obstinately persistent.

COMPLICATIONS.—Many of these have been mentioned in describing the symptoms. Inflammations of the serous membranes—pleurisy, pericarditis, peritonitis—and pneumonia are amongst the most formidable of the complications of chronic Bright's disease. The arteries strained by the high tension not infrequently rupture and give rise to hæmorrhages. The bleeding may take place from the nose, or from the lungs, causing hæmoptysis, or even from the kidneys themselves, the blood appearing in the urine. In these situations the bleeding is rarely dangerous, albeit, occasionally, the pulmonary hæmorrhage may be so profuse as to disable the lungs, and a patient may in rare instances die from excessive hæmaturia. But the most dangerous hæmorrhages are those from the cerebral arteries. Indeed, granular kidney, with its associated cardio-vascular changes, is the most frequent cause of cerebral hæmorrhage.

Cardiac failure with dilatation is one of the most common complications of Bright's disease. It is accompanied by a diminution in the quantity of urine and an increase in the amount of its contained albumen. The oedema of the tissues increases, or, if not previously present, now appears. In addition, oedema of the lungs, as shown by the presence of crepitation at the pulmonary bases, and dropsy of the pleural sacs, result from the cardiac weakness, and their occurrence interferes greatly with the respiratory functions. The changes observed in the cardiac sounds and in the pulse, when the heart fails, have already been detailed.

Oedema of the larynx in some cases causes dangerous and even fatal asphyxia. Severe vomiting and diarrhoea occur occasionally, not rarely as the result of the impurity of the blood, but they may also arise from ulcerative lesions of the gastro-intestinal tract.

The deficient action of the kidneys causes an accumulation in the blood of excrementitious matters ordinarily eliminated. This condition is known as *uræmia*, and is the cause of a great number of symptoms, which will be fully described in the article devoted to that subject. For convenience they will be

here enumerated. In the nervous system we notice headache, muscular twitches and convulsions, coma, and sometimes a hemiplegia independent of a gross cerebral lesion. Sudden blindness or deafness may come on, and mental derangements may occur, generally assuming the form of melancholia, but sometimes of mania. Vomiting, nausea, and diarrhoea of an uncontrollable character are not unusual. Paroxysms of dyspnoea simulating asthma are among the rarer phenomena, but the breathing in uræmic attacks is very prone to assume the Cheyne-Stokes' character.

DIAGNOSIS.—The question of the diagnosis of chronic Bright's disease arises chiefly under the following circumstances:—

(1) When albuminuria occurs persistently without any other serious derangement of health. The points to be relied upon in determining whether in such a case organic disease of the kidneys is present will be found discussed in the article upon **ALBUMINURIA**.

(2) When cardiac disease and albuminuria co-exist. The albuminuria may in this instance be due to venous engorgement of the kidneys, secondary to the cardiac trouble, or it may be the result of chronic Bright's disease, to which the heart affection is secondary. Venous congestion of the kidneys, however, may generally be detected by observing that the urine is scanty, of high specific gravity, and yet contains, as a rule, only a small quantity of albumen, deposits urates, but very few casts, on standing, and contains very frequently a quantity of bile pigment. Moreover, there may be a history of valvular disease of the heart or of some affection likely to have produced it—*e.g.*, an attack of acute rheumatism—and it may appear that the symptoms of cardiac distress, with cyanosis and enlargement of the liver, were present prior to the occurrence of the albuminuria.

(3) When headache, digestive disturbance, or puffiness of the features, or a copious discharge of urine, create a suspicion of chronic Bright's disease, and yet the urine contains no albumen. Either the granular or the amyloid kidney may be present. The urine of the granular kidney is frequently, and often for considerable periods at a time, free from albumen, but it is persistently of low specific gravity, whilst the pulse is of high arterial tension, the heart is hypertrophied, and urinary tube casts are occasionally detected, although they

may easily be overlooked. Further, the excretion of urea is deficient. If, however, the retinal changes be found, the diagnosis is rendered certain.

Although the urine of the albuminoid kidney ordinarily contains a large amount of albumen, cases at times occur in which it is entirely absent. Indeed, the passage of a large quantity of limpid urine of low specific gravity is an earlier sign than albuminuria of amyloid degeneration in the kidneys. Such a symptom occurring after long-continued suppuration, or in the presence of a wasting disease or a cachectic state, should excite suspicion that this change is in progress. If the liver and spleen be coincidentally enlarged, no difficulty would be experienced in coming to a correct diagnosis.

(4) When an outbreak of apparently uræmic symptoms occurs (*see URÆMIA*).

(5) When the signs of acute Bright's disease are present, or when an attack of pneumonia, pleurisy, &c., is accompanied by albuminuria, and it is desired to ascertain whether chronic Bright's disease preceded.

Here the condition of the heart is all important. Cardiac hypertrophy or considerable dilatation, in the absence of valvular disease, would indicate that high arterial tension had preceded the acute attack. The white spots of retinal degeneration would be positive evidence of chronic Bright's disease. Great anæmia in a middle-aged person, and the occurrence of pneumonia or pleurisy on both sides of the body, are also probable indications that the affection is only a complication of chronic kidney mischief.

The diagnosis of the several varieties of chronic Bright's diseases from one another is to be found above in the discussion of the symptoms. It may be convenient, however, to summarize them here.

(a) In the granular kidney the urine is copious, of low specific gravity, and contains but little albumen. The pulse is of very high tension, and the heart is greatly hypertrophied. There is little dropsy. In the retina there are hæmorrhages and degenerative patches, and there is a tendency to hæmorrhage from various organs. The skin is sallow, and there is some anæmia, but it is not extreme in degree.

(b) In the large white kidney the urine is scanty, of high specific gravity, and contains a large amount of albumen. The pulse is of high tension, and there is hypertrophy of heart, which very often subsequently undergoes dilatation.

There is much dropsy. In the retina there are hæmorrhages, but rarely degenerated patches. There is less tendency to hæmorrhage from other organs, but more to internal inflammation than in the granular kidney. The skin is pale, and there is great anæmia.

(c) In the albuminoid kidney the urine is copious, of low specific gravity, and contains a variable amount of albumen, rarely none, usually a considerable quantity. The pulse is of low tension, there is no tendency to cardiac enlargement. There may or may not be dropsy. There are no retinal changes, and there is no tendency to hæmorrhage, or to internal inflammation. The skin is pale, there is great anæmia, and one of the causes of albuminoid disease enumerated below is to be found.

It must again be mentioned, however, that mixed forms, and therefore mixed symptoms, are the rule.

Morbid Anatomy and Pathology of Chronic Parenchymatous Nephritis.

—*Morbid Anatomy.*—The kidney is large and pale, or its surface may show a mottling of red and yellow patches. The *venæ stellatæ* of the surface vary as regards their prominence. On section the cortical portion is increased in extent and is very pale in colour, the medullary portion may appear to be normal or is congested and streaked with deep red lines. The capsule peels off easily, and leaves a smooth or very slightly granular surface, upon which, as a rule, no cysts are seen.

On microscopic examination the changes which are observed are most marked in the convoluted tubes. The tubules are enlarged and distended with the proliferated and swollen epithelial cells. The lumen of the tubule is sometimes almost invisible, so great is the mass of protoplasm bounding it; or, again, it may be blocked by a fibrinous cast. The protoplasm of the cells is very opaque and granular, and often studded with fat globules, while the outlines of the individual cells cannot be easily distinguished. The nuclei of the cells are often invisible on account of the swelling of the protoplasm. On the other hand, the nuclei are sometimes very evident and much increased in number. The hyaline globules described in acute nephritis, are also found in the protoplasm of the cells in chronic nephritis. The basement-membrane of the tubules is thickened.

The glomeruli often show changes consisting of one or other of the condi-

tions described under the head of glomerulo-nephritis, but proliferation of the capsular epithelium and thickening of the capsule itself by successive concentric layers of fibrous tissue are the changes most commonly met with.

The interstitial tissue is rarely normal. It is usually somewhat thickened, especially between the convoluted tubes, and is sometimes infiltrated with leucocytes. The vessels are at times engorged, and not unfrequently hæmorrhages are seen in and between the tubules.

Such is the typical condition of the large white kidney. But it is prone to undergo other degenerative changes. The protoplasm of the cells in the tubules becomes still more granular or fatty, and occasionally pigmented, and finally breaks down into an amorphous débris, which is carried away in the urine. The tubules then collapse, and as the tubules affected are almost entirely those of the cortical portion of the kidney, the thickness of the cortex becomes greatly diminished. At the same time the interstitial tissue becomes increased in amount, especially between the tubules, but also round the blood-vessels, and the glomeruli become diminished in size.

These appearances characterize what is known as the *small white kidney*. It is a late condition, but not a necessary sequence, of the large white kidney, and transition stages between the two are occasionally met with.

Pathology.—The large white kidney is most frequently the result of an attack of acute nephritis which has lapsed into the chronic condition. It may arise also as a consequence of pregnancy (*see* PUERPERAL ALBUMINURIA), and is common amongst beer-drinkers. The average age of its victims has been found to be 28.2 years.

Morbid Anatomy and Pathology of Granular Contraction of the Kidneys.

—The kidney is almost always much diminished in size and weight. Nevertheless, cases are occasionally met with in which the normal size of the organs is retained or even exceeded. The capsule is greatly thickened, and adherent to the underlying gland tissue. It is sometimes impossible to remove it without tearing away the kidney substance. In other cases, again, the capsule peels off with some little difficulty, and leaves, on removal, a surface the appearance of which gives its name to this form of Bright's disease. The surface is of a general reddish colour, on

which are seen numerous small yellowish elevations or granules of a rounded outline. Frequently, and, indeed, in most cases, numbers of cysts appear between the granulations, varying in size, from that of a pin's head to that of a walnut; some are filled with limpid, others with turbid fluid; and others, again, contain a dark glutinous substance.

The kidney is firm on section, and its cut surface reveals considerable atrophy of the cortical portion of the organ, and more cysts are seen in the renal substance.

When a section of the kidney is examined *microscopically*, the interstitial tissue is found to have undergone very great increase in amount, mostly round the blood-vessels and glomeruli, but also in all other parts. In most cases the fibrous tissue is fully formed, yet occasionally its cellular elements are found in excess.

The tubules of the kidney are greatly reduced in calibre; their cellular elements are more or less atrophied, sometimes being entirely absent, at other times fatty and granular. The irregular bulky epithelium of the convoluted tubes is often represented by a layer of cubical cells much smaller than those from which they originated.

The glomeruli suffer equally with the tubules. They are much smaller than normal by reason of the pressure exerted upon them by the growth of fibrous tissue around, and, to a less extent, on account of the atrophy of the glomerular tuft itself from increase of the interstitial tissue between its capillaries. Often the whole glomerulus is transformed into a fibrous, hyaline, or colloid mass of absolutely no functional utility.

The arteries show a considerable thickening of their walls which may affect all three coats. The adventitia is thickened by a great increase of its fibrous tissue, the middle coat shows a much greater amount of muscular fibre than is normal, and the intima, between the elastic layer and the internal endothelium, is occupied by a fibrous or amorphous material which projects into and occasionally blocks the lumen of the vessel.

In the granular kidney of gouty origin streaks of a yellowish white colour are often seen in the pyramidal portion of the gland, and these, on microscopic examination, are found to be either amorphous, consisting of urate of soda, or they may exceptionally be crystalline, and composed of uric acid.

It has been shown by Dickinson, and

again by Thoma, that such a kidney offers much greater resistance to the injection of its blood-vessels than does a normal kidney.

Pathology.—The process by which this state of kidney is attained has received several explanations. It has been thought that an inflammation starts in the epithelial elements, and that from the atrophy of these the tubes containing them collapse. The fibrous tissue would, according to this view, be the altered remains of the collapsed tubes. Again, the process has been looked upon as from the first interstitial and yet inflammatory—a chronic interstitial nephritis. Finally, the fibrous tissue has been thought to be the result of a degenerative overgrowth, believed by some to be confined to the kidney, by others to be part of a widely spread fibrous overgrowth in all parts of the body, but specially connected with the arteries.

The granular contracted kidney may result from an attack of acute nephritis, but not so frequently as does the last form described. It is specially related to the gouty and syphilitic diatheses. Chronic lead poisoning is a frequent cause, and experimentally the disease has been produced by dosing animals for a considerable time with lead or cantharides. Alcoholic excess, and especially spirit drinking, is believed by most observers to be productive of this form of kidney disease.

The average age of patients suffering from the affection is 50.2 years. It is more common in the male sex, and a hereditary transmission has been occasionally noted. Like the large white kidney, it is sometimes the final stage of the renal disease of pregnancy.

Morbid Anatomy and Pathology of Albuminoid Degeneration of the Kidneys.—The kidney in its typical form is enlarged, and much paler than normal, though mottled on its surface by the red *venæ stellatæ*. It cuts firmly, and the pale, bloodless section shows an increase of the cortex in depth, and has a peculiar, glistening, bacon-like appearance. The glomeruli stand out upon the cut surface as bright, pale points. The medullary portion appears by contrast to be of a brighter red than is usual. The capsule peels off easily, and leaves on removal a smooth surface. The change becomes more evident, and can easily be seen when only slight in amount, if colouring agents are used for which the albuminoid parts have a special affinity. For naked-eye purposes a cut surface of the kidney may

be treated with liquor iodi, which tinges the affected parts of a mahogany-brown colour, the remainder of the kidney taking a yellow tinge. For microscopic examination a solution of methyl-violet is preferable. This colours the albuminoid parts a reddish purple, the others blue. By these reagents the smallest amount of the change can be readily detected.

On *microscopic* examination the parts affected by the albuminoid change appear translucent, glistening, and homogeneous unless coloured by the reagents mentioned. The change is most marked in the glomeruli and the walls of the blood-vessels, but is also found in the interstitial tissue and in the basement membrane of the renal tubes; rarely in the epithelial cells. The tubules are described by Dr. Dickinson as more rigid and widely open than is normal. In certain cases the change is limited to the vessels of the medullary portion of the kidney (*vasa recta*), and leaves the glomeruli intact.

Such is the typical condition of the albuminoid kidney, but very frequently it is combined with an over-growth of interstitial fibrous tissue, which causes its surface to be rough and coarsely granular, resembling that of the red contracted kidney, while its volume, too, may then be diminished instead of increased.

The nature of albuminoid degeneration will be found discussed elsewhere.

Pathology.—This change in the kidneys, as in other parts, is caused by prolonged suppuration, by disease of bones and joints, by tuberculosis, and by the syphilitic, mercurial, or malarial cachexiæ. It is associated sometimes with lead poisoning, gout, rickets, leucocythæmia, Hodgkin's disease, and slowly growing tumours.

PROGNOSIS OF CHRONIC BRIGHT'S DISEASE.—It has been recorded that albuminoid disease of the kidney, if only slight in degree, has been recovered from when the original suppurative affection has been removed. With this exception, cases of chronic Bright's disease must be looked upon as incurable, and as tending to a fatal issue. Yet the duration of the disease is subject to wide variations, and may be surprisingly prolonged when proper care and treatment are adopted. Comparing the several varieties of the disorder, we find that the large white and the albuminoid kidneys kill their subjects in a much shorter time than does the small red kidney. The ultimate cause of death to which the

kidney changes tend to uræmia, from deficient elimination of excrementitious matter. This perhaps most frequently results with the large white kidney, but in all varieties the complications which may occur are so numerous that the patient usually dies of one of them before a fatal uræmic state can appear, although minor degrees of uræmia are common. Amongst the signs which render the prognosis very unfavourable are—(1) A diminution in the amount of urine, which previously was copious, while at the same time its specific gravity is not higher than before; (2) a very low daily excretion of urea; (3) the occurrence of severe uræmic symptoms, or (4) of pneumonia, pleurisy, or pericarditis. Excessive dropsy, cardiac failure, and œdema of the lungs are dangerous symptoms; nevertheless, they are more amenable to treatment than those just mentioned. The white degenerative patches in the retina may appear when the patient is apparently in otherwise good health, yet they always indicate a severe degree of kidney affection, and the disease rarely lasts more than two years after their occurrence, unless it be the result of pregnancy (*see PUERPERAL ALBUMINURIA*). The longer the duration of the disease, the shorter, naturally, must be the expectation of life.

TREATMENT OF CHRONIC BRIGHT'S DISEASE.—The aims of treatment must be (1) to relieve the kidneys of any undue irritation, and to assist them in their eliminatory functions by promoting the action of other organs; (2) to enable the circulatory system to adapt itself to the altered conditions of peripheral resistance; and (3) to combat the distress and danger to which the patient is subjected by the occurrence of complications.

The skin must be maintained in a state of activity as nearly healthy as possible. Flannel must be worn, and warm baths and friction occasionally employed to stimulate the cutaneous circulation. The Turkish bath is sometimes of value, but it should only be used when the heart is powerful, and always with caution. Moderate exercise is to be taken, and the bowels should be induced to act at least once in the day—if necessary, a morning dose of purgative water being used for this end. The diet should be light, and contain but little nitrogenous matter. Milk and milk puddings are well borne as a rule. When the arterial tension is high, as is usually the case in granular kidney, it is best to order fish

or meat only once in the day, the other meals being of lighter character. In other cases, however, and especially in those of albuminoid kidney, nutrition must be maintained by a more liberal dietary. A moderate amount of light wine, or a glass of bitter ale daily may be permitted when the patient has been accustomed to a stimulant. Spirits and the stronger wines are generally harmful. All conditions which give rise to irritation of the kidneys, such as exposure to lead poisoning, alcoholic excess, and the gouty state, should be removed by suitable means. Any source of prolonged and exhausting suppuration should be treated by the surgeon, so as to prevent any increase of albuminoid change where such exists.

All forms of Bright's disease tend to the production of anæmia, and therefore it is desirable in nearly all cases to administer iron in some form. The citrate of ammonia and iron may be given in 10 to 15 grain doses thrice daily, or the tincture of the perchloride in 15-minim doses. Rarely will any difficulty be experienced in the assimilation of the drug if care be taken to keep the digestive organs in healthy activity. Thus, the use of iron must be suspended if the tongue be dry and coated, and the gastric condition must then be remedied by suitable treatment. The bowels, too, must not be allowed to become constipated, and therefore the astringent perchloride of iron is well combined with 20-grain doses of sulphate of magnesium. When the heart is greatly hypertrophied and the arteries are tense, it is dangerous to give iron, unless, at the same time, the circulatory condition be treated in the way to be presently described.

In cases of granular kidney the loss of albumen by the urine is generally very slight, and needs no special attention. In other forms of the disease, however, the loss is so great as to invite the physician to inquire whether measures might not be taken to control it. So far, however, no reliable remedies with such an action have been discovered.

From the account which has been given of the circulatory changes in Bright's disease it is evident that a certain degree of increased arterial tension is unavoidable, and it must be the object of the physician to prevent the tension increasing beyond a limit which may be considered normal for the disease, and at the same time to insure that the heart shall put forth such an extra

amount of force as shall suffice to overcome the peripheral resistance. Too great tension is to be avoided, because of the increased strain upon the heart and the risk of rupture of an artery in a dangerous situation; too great depression of the circulation causes danger from the liability to œdema of the lungs, dropsy of the serous sacs, and deficient excretion of urine from defective circulation through the kidney. It is a mean between these two conditions which it is desirable to maintain in Bright's disease. When the pulse is of only slightly increased tension, the heart is beating regularly, the heart sounds are normal, and the assimilative functions are in good order it is unwise to interfere with the existing condition. All that is necessary is for the patient to follow general hygienic rules.

It is rare, however, for this condition to be spontaneously maintained for a lengthened period. The patient may perhaps present himself with signs of cardiac dilatation, slight anasarca, and œdema of the lungs, a pulse of "virtual tension," and a deficient excretion of urine. In such a condition treatment must mainly be directed to sustaining the heart. Acid. nitric. dil. or acid. nitromur. dil. $\mathfrak{m}\mathfrak{x}$ - \mathfrak{xv} , with liq. strychniæ $\mathfrak{m}\mathfrak{v}$ and tinct. digitalis $\mathfrak{m}\mathfrak{v}$ - \mathfrak{x} , should be given three times a day, or even every four hours. Tincture of strophanthus and citrate of caffeine may sometimes be substituted for the digitalis with advantage. A small dose of pil. hydrarg. is occasionally advisable to relieve the peripheral tension before which the heart is failing, but in severe cardiac failure it is best omitted. Or, again, the patient may complain of throbbing headache, drowsiness, and yet insomnia; the pulse is of high tension, the heart beats forcibly, and, on stethoscopic examination, the first sound of the heart is found to be prolonged or reduplicated, and the second sound greatly accentuated at the aortic cartilage. In this condition 5 grains of calomel should be prescribed, followed in a few hours by a saline purgative draught. Another, but smaller, dose of calomel should be given after an interval of two or three days if the symptoms have not entirely subsided, and in the meanwhile saline remedies, such as the tartrate of soda and potash in \mathfrak{i} -drachm doses, together with the citrate of potash in 20-grain doses, may be given three times a day. Given in this way it is very rare for symptoms of salivation to follow the use of calomel.

By these two methods of treatment it is possible to control to a great extent the variations of the circulatory system beyond that condition which may be considered normal for the disease.

When excessive dropsy exists, the abnormal amount of fluid may be removed in various ways. If anasarca of the legs be specially prominent, it is best treated by the insertion of Southey's drainage-tubes beneath the skin. Large amounts of fluid will drain away in a comparatively short time, and there is but little risk of erysipelas or inflammation of any kind being set up round the puncture. The older treatment by incision or simple puncture of the skin is often followed by severe cellulitis. Southey's tubes also offer a convenient and safe way of removing fluid from the abdominal cavity, though here the use of an ordinary trochar and canula of small size is more advisable. Cathartic purgatives are of great use in removing dropsical effusions. The compound jalap powder in half-drachm or larger doses is the most generally efficacious, and may be administered twice or thrice a week. Gamboge, scammony, and colocynth may also be given, but commonly the jalap powder is sufficient to produce the desired effect. If, however, the dropsy should be general, and should threaten the life of the patient by interfering with vital functions, the most powerful drug which can be used is elaterium, in doses of one-fourth of a grain. It is important to watch the patient carefully when such violent purgatives are being administered, lest the diarrhœa induced should become intractable.

If free action of the skin can be procured, material relief is often afforded to dropsical and often to uræmic symptoms. Hot baths are most efficacious in promoting perspiration. They can be applied in the form of the blanket bath, already described, or the ordinary hot-water bath, or the vapour bath. The vapour bath can readily be extemporized without removing the patient from bed. The patient should be wrapped loosely in blankets, and the bed-clothes raised by a bed cradle. The nozzle of a steam kettle is now to be introduced beneath the clothes, due precautions being taken to prevent the skin being scalded by the too direct contact with the steam. The steam is allowed to pass for fifteen or twenty minutes, and at the end of that time the patient is to still remain wrapped in the blankets, and will usually perspire profusely. Other diaphoretics,

such as the compound ipecacuanha and compound antimony powders and the liquor ammonii acetatis, are less reliable. The injection of one-third of a grain of pilocarpin subcutaneously causes profuse perspiration, and, if the patient be directed to expectorate the saliva, the flow of which is, at the same time, much increased, the tendency to vomit can often be avoided. Nevertheless this drug is not so serviceable in general dropsical conditions as when used as a rapidly acting remedy in uræmic attacks.

When the urine becomes scanty, diuretics are called for. Of these the most efficacious are the acetate and citrate of potash, nitrous ether, and citrate of caffeine. The scanty secretion of urine can often be best treated by attention to the state of the circulatory system and the administration of remedies in the manner already directed. Calomel given as directed above often acts as a pronounced diuretic. In Bright's disease even more than in other conditions do diuretics seem to be uncertain in their action.

Dropsy is sometimes persistent in spite of all these remedies, and it is then desirable to administer iron, acids, and general tonics freely. Œdema of the glottis may call for special treatment, either by scarification of the swollen parts or even in extreme cases by tracheotomy.

When inflammations of the internal organs occur as complications, they must be treated on ordinary principles, remembering, however, that lowering remedies are rarely admissible. The subjects of Bright's disease are, as a rule, peculiarly intolerant of opium, and it is recommended by most authorities that this drug, if administered at all, should only be given in minute doses, and its action carefully watched. Some doubt has, however, of late been cast upon this statement, and opium has even been given in uræmic convulsions without obvious bad effects. Further experience is necessary before such a mode of treatment can be recommended with confidence. Similarly, too, dyspeptic symptoms must be treated as if arising independently of Bright's disease. Arsenic is often of great use in such conditions.

The treatment of the various conditions caused by uræmia will be found in the article upon that subject.

ROBERT MAGUIRE.

BROMISM.—When the salts of bromine are given in excessive doses,

certain phenomena are wont to appear which are known by the above name. Bromide of potassium, being the salt in most common use, is generally the cause. The prominent *symptoms* are headache, apathy, somnolence, impaired muscular power, dryness of the mouth, and anæsthesia of the soft palate and pharynx. The skin is pale, the heart's action feeble, and the extremities cold; nausea and flatulence are often complained of, and sometimes there is diarrhœa; catarrh of the bronchial tubes is common, as also loss of sexual power and appetite, with atrophy of the mammae or testicles. In advanced cases the patient becomes much emaciated, and falls into a state bordering on imbecility. A characteristic acneiform eruption on the skin is one of the earliest and most constant phenomena. It is fully described under the head of MEDICINAL RASHES.

Treatment.—The dose of the drug should be immediately diminished, or its use given up altogether. The addition of from 3 to 5 minims of liquor arsenicalis to the mixture containing the bromide sometimes prevents the appearance of the eruption.

BRONCHIAL CATARRH.—The simplest form of acute inflammation of the bronchi resembles closely the simple nasal catarrh, with which it is very frequently associated. A "cold in the head" is said to have "settled on the chest."

The *symptoms* are:—A slight sense of tightness or uneasiness across the front of the chest; a short, dry, irritative cough, which seems to aggravate this uneasy feeling; very slight expectoration of thin, sticky mucus; and a sensation of chilliness, especially about the neck and shoulders, with a feeling of depression and lassitude. There is generally some sore throat and hoarseness, and occasionally a slight rise of temperature and increase of the pulse rate. It attacks persons of all ages and both sexes, but in very unequal degree. Some individuals display a marked susceptibility to bronchial catarrh, and this persists throughout life, generally resulting before middle life in chronic bronchitis. In children, the simple catarrh is very prone to spread to the smaller bronchi, or even to the vesicular tissue, and set up broncho-pneumonia. Cold and damp weather at any season of the year is the most common exciting cause, but almost any source of chill may be held responsible. In the large majority of cases the

physical signs of this condition are limited to the occasional presence of a few rhonchi in the larger tubes.

The *pathological changes* in bronchial catarrh are limited to hyperæmia with slight swelling of the mucous membrane of the larger bronchi.

The *treatment* consists in preventing, as far as possible, the aggravation of the disease by outside influences, such as the inhalation of cold damp air and exposure to sudden changes of temperature. The patient should be kept indoors and in one room, and protected from draughts. A mustard and linseed poultice should be applied to the throat and upper part of the chest, and steam, medicated with compound tincture of benzoin (one teaspoonful to a pint of water at 140°) inhaled for about ten minutes at a time, three or four times a day. These measures, followed by a dose of Dover's powder (grs. v-x) at night, and a gentle saline purge (Friedrichshall or Hunyadi Janos water) the next morning, will often suffice to cut short an attack. A draught containing vin. ipecac. ℥v and liq. ammonii acetatis ʒss may be given every four hours if the case be sufficiently severe to require the use of drugs. In some patients an attack may be cut short by 5-minim doses of liq. morphinæ hydrochlor., repeated every hour until five or six have been taken, or by quinine in larger doses (grs. v-x). The diet should be somewhat reduced, and stimulants avoided until the febrile symptoms have subsided. The symptoms of acute catarrh usually pass quickly off, or the disease spreads further into the lung. A condition of non-febrile or passive catarrh is, however, very apt to linger after the active form has subsided. This is generally best treated by a change of air. Active exercise is beneficial, but it should be short, sharp, and vigorous, and not protracted so long as to cause fatigue. Cold sponge baths at a temperature not lower than 65° should be taken each morning on rising, the feet being at the same time immersed in hot water. The diet should be somewhat more nourishing than that to which the patient is habituated, and stimulants in the form of full-bodied wines, such as port, sherry, and Madeira, are to be recommended. Tonics, especially preparations of iron and quinine, are always useful in such cases.

Attention to the regular action of the bowels is an important detail in the treatment of bronchial catarrh. The use of the time-honoured blue pill or of

the more modern hepatic purgatives—podophyllin (gr. ¼-j), euonymin (grs. j-ij), and cascara sagrada (℥x-xx of the liq. extr.)—should not be neglected.

E. CLIFFORD BEALE.

BRONCHIAL GLANDS, Diseases

of the.—The chain of glands running beside the bronchi, and particularly those situated in the angle between the right and left bronchus at the bifurcation of the trachea, are subject to enlargement from many causes, especially in children and young persons. From their anatomical position it is obvious that any marked degree of enlargement is very likely to in some way affect the important structures which lie in close relation with them, and the presence of a group of *symptoms*, including cough of an irritative kind, not attended with much expectoration, pain, generally referred to the upper dorsal vertebræ and between the scapulæ, spasmodic dyspnoea, dysphagia, and an alteration of the voice, is considered by some writers as sufficiently clear evidence of enlargement of these glands. All these symptoms, however, may be brought about by other means. Hence the positive diagnosis of the condition is a matter of great difficulty. The physical signs also as described are scarcely more trustworthily than the symptoms.

The glandular enlargement must be extreme in order to affect the percussion note in the interscapular region, a situation in which it is admittedly difficult to be sure of slight differences only in the sound. There is also the fact that the glands, even when enlarged, lie chiefly upon the bodies of the vertebræ, and are prevented from contact with the chest wall posteriorly by the intervention of the lung, which is closely applied to the sides of the spine. The glands at autopsies on adults are often seen to be much enlarged, without any obvious change in the lumen of the tubes, one reason being that the bronchial cartilages are sufficiently strong to resist the pressure. There is, however, little doubt that in children narrowing may result. If, as is rarely the case, this be extreme, the respiratory sound on the affected side may be diminished in intensity.

Pathology.—All impurities passing through the lymphatics into the bronchial glands are liable to be arrested there, the glands acting as filters. Organic impurities, such as carbonaceous particles, are stored up in the meshes of the glands, without giving rise to any

inflammatory action; specific poisons, such as syphilis and tubercle, cause an appreciable degree of irritation and consequent swelling. Amongst other causes of enlargement are:—Simple hypertrophy, usually associated with passive enlargement of other glands in the body or with the general symptoms of Hodgkin's disease; bronchitis or any other non-specific affection of the lower respiratory passages, especially asthma and whooping cough, and malignant growths. Of these, tubercle is by far the most common, but the actual enlargement to which it gives rise is not usually very great. Syphilis is more rarely met with, but it may set up much greater interstitial changes in the gland. Morbid growths—*e.g.*, lympho-sarcoma about the root of the lung—generally begin in the bronchial glands or the peri-bronchial tissue, but in many of the recorded cases of cancer of the lung, either localized or infiltrating, the glands have been altogether unaffected. Acute inflammation, even going on to suppuration, has in rare instances been observed, and may set up general pyæmia. Chronic inflammation, leading at times to caseation or calcareous changes, is more frequently met with, sometimes as an apparently independent affection, and at others as a part of general scrofulous degeneration of the lymphatic glands. Caseating glands not infrequently give rise, by pressure and irritation, to ulceration and even perforation of a blood-vessel, usually with a fatal result. They may also invade the pericardium, and constitute one cause of purulent pericarditis.

Other pathological conditions clearly attributable to the pressure of bronchial glands are bronchiectasis and diffuse gangrene of the lungs. In such cases an enlarged gland has been found to have perforated the bronchial wall and discharged its contents into the air passages; occasionally, also, a communication has been, at or about the same time, established between the gland and the œsophagus, thus throwing the œsophagus and trachea into communication through the medium of the gland.

Treatment.—The diagnosis of this condition being almost impossible, very little need be said about its treatment, which must depend upon the nature of the enlargement. Large doses of iodide of potassium (grs. v-xxx) in the early stage, and of calcium sulphide (gr. $\frac{1}{2}$ -j) in the later stages, have been recommended as of service.

E. CLIFFORD BEALE.

BRONCHIECTASIS.—Dilatation of the bronchi is a lesion often found in association with chronic pulmonary disease, but of rare occurrence as a primary affection. It may be met with in (1) chronic bronchitis and emphysema; (2) chronic phthisis; (3) hypostatic pneumonia, with collapse; (4) cirrhosis of the lung (fibrosis); (5) collapse secondary to pleural effusion; (6) pressure on, or obstruction of, a bronchus by growths, or enlarged and infiltrated mediastinal glands; (7) chronic pneumonia; (8) catarrhal pneumonia, especially in children; (9) pulmonary gangrene; (10) as the result of the presence of a foreign body in the air passages, and in some other conditions.

Owing to the frequent occurrence of the condition in chronic phthisis, the apex of the lung is its most frequent site, but, that disease apart, the bronchi at the base are most commonly affected. A tube may be more or less uniformly dilated for the whole or only a limited extent of its course, the *cylindrical form*; or it may be dilated in isolated places, forming sacculi or pockets, the *sacculated form*. A single tube may be thus affected, or the change may be present throughout a whole lung, the so-called *turtle lung*. The dilated tube is seldom of uniform diameter throughout; more often at short intervals the lumen is narrowed by the projection of fibrous septa. The wall is generally smooth and glistening, but may become ulcerated if any septic or infective (tubercular) complication arise; it may be of less than normal density or considerably thickened, the result of inflammatory changes in the mucous membrane, the latter often presenting a velvety appearance. The tubes may be filled with pale, viscid mucus or with pus, or be quite empty; at times the contents are purulent and fetid.

The pulmonary tissue surrounding a dilated bronchus may be unchanged, but, if many neighbouring tubes be affected, the intervening tissue is almost invariably condensed from the presence of fibrous changes (*see LUNGS, CIRRHOSIS OF*).

The *symptoms* present much variety, and depend greatly upon the nature of the primary disease. If the dilated tubes be shut off from communication with the other bronchi, or if their contents remain unchanged and aseptic, no symptoms proper to the condition will arise. Paroxysmal cough, with the expectoration of a considerable quantity of muco-purulent material at intervals, followed by a period of almost complete freedom from

cough, is the most characteristic symptom of the existence of bronchial dilatation.

Should the sputum become fœtid, it may be found, on microscopical examination, to contain soft, friable, yellow masses (Traube), vegetable organisms, and needle-shaped crystals; to these latter the peculiar odour is believed to be due (see EXPECTORATION).

The only *physical sign* on which reliance can be placed is the appearance of well-marked cavernous breathing (especially if at the base of the lung), following the expectoration of a large quantity of muco-pus and the gradual disappearance of the sign as the secretion re-accumulates. If this sequence of events be clearly and repeatedly observed, it is highly suggestive of bronchiectasis; it may, however, occur when an empyema has opened into the lung, and is altogether absent in many cases. A peculiar wavy and hollow character of the respiratory sounds is also at times present in bronchiectasis.

The *prognosis* will greatly depend upon the nature of the primary disease. If the condition follows collapse of the lung, the result of pleural effusion, or arises from the lodgment in one of the bronchi of a foreign body which is subsequently expelled, recovery may occur and fairly good health be enjoyed. If, however, bronchiectasis occur as a complication of any of the other affections mentioned at the beginning of the article, the condition will probably be permanent.

If the expectoration lose its fœtid odour and gradually diminish in quantity, it is probable that the dilated tubes are either becoming obliterated or shut off from communication with the air.

Treatment.—The results of operative treatment for the relief of this condition are extremely unsatisfactory and disappointing. Some successful cases of opening and draining bronchiectasia have, it is true, been reported, but they are not free from the suspicion that the condition was really one of localized empyema in communication with a bronchus. There is now a fairly general consensus of opinion that, so far as surgical treatment is concerned, these cases are best left alone. The establishment of an opening in the chest renders the cough less effective, and, should the secretions be retained and septic changes occur, the condition of the patient is worse than before the operation. A more important objection, however, is that the affection is rarely confined to

a single bronchus, hence it is likely that many dilated tubes will remain undrained. The inhalation of creosote or a 40 per cent. solution of carbolic acid pulverized by a steam spray apparatus may be of use in diminishing the fœtor of the expectoration.

Change to a dry and bracing air and the administration of cod-liver oil, quinine, and the syrup of the hypophosphites are useful aids to the improvement of the general health.

E. CLIFFORD BEALE.

BRONCHITIS, ACUTE.—Acute bronchitis differs from simple bronchial catarrh only in the degree of its severity. It becomes more serious in direct proportion to the number of tubes inflamed and to their calibre, inflammation of the finest capillary tubes being one of the most serious conditions to which the lung is liable.

The *symptoms* are those of bronchial catarrh, but are in every respect more marked. The feeling of weight or tightness behind the sternum amounts to a sensation of rawness, which is aggravated to actual pain by the irritating cough. The sputum, at first thin, becomes, later on, thicker and muco-purulent and may at times be slightly streaked with blood. There is not much dyspœa as a rule. The cough is often paroxysmal, coming on in sudden bursts, and giving rise to much distress. The general feeling of illness and chilliness is more marked; there is frequently a rise of temperature, with loss of appetite, and thirst. Some cyanosis is occasionally present, or the face may be dusky or slightly flushed.

Physical Signs.—The movements of the chest vary in proportion to the seat and extent of the disease, the upper part being generally expanded more than usual if both bases be extensively affected. Expiration is laboured and prolonged. In severe cases there may be considerable inspiratory recession of the supra-clavicular and epigastric regions. The percussion note is generally normal. On auscultation the signs vary with the stage of the disease. The breath sounds may be diminished in intensity or harsh, and both movements of the chest may be accompanied by adventitious sounds. These vary with the amount of swelling of the lining membrane present in the affected tubes, and may change considerably within a short time. Sibilant and sonorous rhonchi are generally

present, or may be elicited by cough, and bubbling râles are frequently heard, especially over the lower lobes. Sometimes, however, even in severe cases, all adventitious sounds may be absent. Neither vocal resonance nor vibration are materially affected, but rhonchal fremitus can often be distinctly felt.

Ætiology.—Acute bronchitis may be the direct consequence of a chill in healthy persons, but is very frequently associated with some other disease of which the patient is the subject, and particularly with affections of the heart or kidney, or with emphysema or any condition which interferes with the general circulation. The exanthematous fevers, rickets, alcoholism, phthisis, gout, and rheumatism are frequently attended with more or less bronchitis, and in children the irritation of teething or the presence of intestinal worms may act as exciting causes. An attack leaves the patient with increased susceptibility to a recurrence of the disease.

Post-mortem Appearances.—The mucous membrane lining the tubes is red and congested, sometimes almost purple in colour, and covered in places with sticky and adherent muco-pus. The finer tubes appear to be somewhat dilated, although their lining membrane is often rather swollen. On cutting off a small portion of the lung and gently squeezing it, small beads of purulent matter will ooze out of the minute tubes, and this test affords the most trustworthy evidence of inflammation within them. Care is necessary, however, to distinguish between actual pus and the yellowish froth which is found in a large majority of healthy lungs.

The minute *pathological changes* are briefly as follows:—The ciliated epithelium is detached, the basement membrane thickened and œdematous and covered with transitional epithelial cells and leucocytes, the lymph spaces beneath it filled with leucocytes, and the mucous glands swollen.

Treatment.—In the treatment of acute bronchitis success often depends upon the recognition of some special factor in the case—for example, its association with gout or some other diathetic or local condition. From the outset the patient should be kept in bed, the temperature of the room being maintained at a level of about 65°, and the atmosphere being charged with steam. To steam a room effectually and rapidly, a few gallons of nearly boiling water should be poured into a large flat

bath placed on the floor. A considerable amount of moisture is then taken up by the air, and can be maintained by the use of the ordinary bronchitis kettle, but this latter apparatus alone is too feeble to make much alteration in the hygrometric state of the air, although it may maintain the moist condition, when once established, for a considerable period. In cases of bronchitis complicated by or accompanying renal disease the use of steam is not advisable, especially if dropsy be present. Care must be taken, if steam be used freely, to prevent the patient being chilled, an event very likely to happen if the temperature of the room be allowed to fall.

Diaphoretic drugs are of great service in the early stages, vinum antimoniae ℥x–xv, or vinum ipecac. ℥x–xv, with liq. ammon. acetat. ℥ss–℥j and sp. æth. nitrosi ℥ss, given every four hours, being a most useful combination. If there be difficulty in getting the skin to act, hot-air baths may be given as the patient lies in bed by means of a spirit-lamp and a large cradle. A “jacket” poultice of linseed, or mustard and linseed, changed every three hours, is a useful but rather troublesome local application.

If much pain be present in the front of the chest, relief may often be obtained by friction with a stimulating liniment, such as the lin. terebinth. acetic. of the Pharmacopœia. A few drops of oil of turpentine sprinkled on a very hot flannel compress will often relieve the pain and soothe the cough at the same time, as the vapour of the turpentine passes upwards and is inhaled.

A mercurial purge (pil. coloc. co. et hyoscy. grs. ij with hyd. subchlor. grs. ij), followed on the second day by a saline laxative (mag. sulph. grs. xxx, mag. carb. grs. x, sod. sulph. grs. xv, aq. menth. pip. ℥j), is generally advisable at the beginning of an attack. When expectoration becomes free and the skin is moist, much relief may be afforded by expectorants, such as tinct. scill. ℥xx, ammon. carb. grs. v, tinct. nucis vom. ℥x, infus. serpentariae ℥j; or syrup. scill. ℥xxx, acid. hydrobrom. dil. ℥xx, sp. chloroform ℥xv, aq. ℥j. Alcoholic stimulants, and especially brandy, are of great value in cases of cardiac weakness, although they need not be used very freely. Opium, whether to relieve cough or to procure sleep, should be used with the greatest caution, and not employed at all for the very young or the aged. Chloral (grs. ij–v) with vinegar of squill (℥xxx), or syrup of tolu (℥xl–lx) is useful in allay-

ing the spasmodic bursts of coughing. Chloral alone (grs. v-xv), or in combination with ammonium bromide (grs. v-xx), will act efficiently to produce sleep, but it should not be used when the heart's action is feeble, or when any cyanosis is present. In such cases, bromide of ammonium (grs. xxx) with tinct. hyoscyam. (℥xxx) and camphor water is to be preferred. In a few cases there may be a degree of engorgement of the right side of the heart needing relief by venesection.

In children the amount of secretion is often very great, and its evacuation ought to be encouraged at intervals; the patients should even be waked at night for the purpose. In old and young alike an emetic is often the only available means of clearing the tubes for a while of the suffocating quantities of mucus. One or two table-spoonfuls of ipecacuan wine should be employed for children, and sulphate of zinc (grs. xv-xxx) for adults.

The diet must be regulated by the powers of the patient. During the early stages, where appetite is lost, the frequent administration of small quantities of nourishing food in a fluid form is indicated, but there is no advantage to be gained by restricting the diet when once the appetite has returned.

E. CLIFFORD BEALE.

BRONCHITIS, ACUTE CAPILLARY.—A form of bronchitis in which the smaller capillary tubes are mainly attacked. It may occur as an independent affection, but more often follows inflammation of the larger tubes or complicates some disease of an inflammatory nature in another organ. It is always a most serious condition, particularly when complicated with emphysema. It is rather more common in children than in adults, but is more fatal to the latter.

Symptoms.—From the very beginning of the attack the disease presents alarming symptoms; a sense of tightness and oppression in the front of the chest comes on quickly, and rapidly increases; this is followed by urgent dyspnoea, either paroxysmal in character or continuous; a short and extremely irritating and persistent cough, at first dry, but shortly afterwards attended by viscid or ropy sputa; sweating, restlessness, and extreme anxiety. The pulse is rapid and bounding, the temperature slightly raised, and the heart's action excited and forcible.

Physical Signs.—In the early stage there is often but little to be heard in the chest except a slight diminution of the inspiratory sound at the bases, with a few small crackling râles scattered over the same area, the percussion note being unaltered. In a short time, however, these râles become audible over a larger area of the pulmonary surface, and acquire a peculiar hissing character, being accompanied by other adventitious sounds according to the amount of mucus present in the tubes. If, as is frequently the case, collapse of many lobules should occur, the inspiratory sound becomes still feebler, and, if the inflammatory process extend to the alveoli, the signs of broncho-pneumonia will be added to those already present.

Unless the attack can be cut short, the patient rapidly shows symptoms of failing power, sinks down in the bed, and ceases to expectorate. Extreme exhaustion comes on, cyanosis, with engorgement of the venous trunks, sets in, albumen appears in the urine, the temperature falls, the pulse becomes feeble and thready, and delirium follows.

The breathing now is shallow and feeble, the period of anxiety and distress seems to have come to an end, the patient usually loses consciousness, and dies quite quietly, although slight convulsions may sometimes occur.

Diagnosis.—The affection is not likely to be mistaken for any other condition except that of œdema of the lungs. The rapidity with which the symptoms are developed and their severity form a sufficiently striking contrast with the more insidious progress of pulmonary œdema.

The *prognosis* in this form of bronchitis is always unfavourable, except in those rare instances in which it occurs independently of any other disease.

The *post-mortem appearances* are those of ordinary bronchitis, but intensified. The pulmonary tissue is more acutely inflamed, and exudes much fluid blood on section; the minute tubes are often found full of pus, and frequently dilated. Not unfrequently, however, a certain amount of œdema is present at the same time.

Treatment, if it is to be of any effect, must be applied early and energetically. Counter-irritation over the bases of the lungs, or over any point where the inflammation has set in, should be employed with vigour. Dry cupping is sometimes effective, but in the more severe cases it is wiser to abstract blood freely by cupping, provided it is done before the disease has spread over a

wide area. The severity of the general symptoms at the outset must be taken as the guide in deciding to make use of it. Stimulants in the form of carbonate of ammonia (grs. v.), ether (℥xx—5j), and brandy must be used from the beginning of the attack. Digitalis is sometimes called for, but in the majority of cases very little can be done by the use of any special drugs.

Energetic treatment may sometimes check the disease before it is far advanced, and the case must then be regarded as one of ordinary bronchitis.

E. CLIFFORD BEALE.

BRONCHITIS, CHRONIC.—

Chronic bronchitis may occur as an independent disease or as the result of repeated attacks of acute bronchitis. In either form it is almost always associated with chronic changes in the lungs and other organs which may be more serious in their consequences than the affection of the bronchi. The chronic pulmonary changes are—(1) emphysema, (2) collapse of lung, (3) dilatation of bronchi, (4) chronic phthisis, (5) gangrene of lung, and (6) pleurisy. Certain diathetic conditions, especially gout, have a definite influence in the production and maintenance of a tendency to chronic bronchitis, but they are often difficult to recognize with certainty.

The *symptoms* in the uncomplicated form resemble those of bronchial catarrh, but there is usually much purulent expectoration. A sense of oppression in the front of the chest is frequently complained of, but usually corresponds to some slight exacerbation of the condition. There is always some degree of dyspnœa, varying in amount with the activity of the inflammatory process and with the nature of the secondary changes in the lungs. When complicated with emphysema, dyspnœa is a characteristic symptom of the disease. The dyspnœa often occurs in paroxysms not unlike those of asthma, the so-called "bronchial asthma," a difference, however, is to be noted in that the expiratory effort is much more laborious and prolonged than in the case of spasmodic asthma. Much distress is generally caused by the cough, which is peculiar in character, and apt to come on suddenly. The patient takes a long breath and coughs a great number of times in succession during the same expiratory movement, until the chest seems to be fairly emptied of air. This necessitates a pause for inspiration; after which a second series of coughs begins

as soon as the lungs have been sufficiently inflated to permit of it.

Physical Signs.—The chest is rounder and fuller than normal, and does not move much on ordinary quiet respiration. When associated with emphysema, it is hyper-resonant, the normal cardiac and hepatic dulness being often completely masked. On auscultation the inspiratory sound is found to be weaker than normal, and is followed by a long, wheezing, expiratory sound. The breath sounds are often accompanied by rhonchi, some deep toned and snoring, others high pitched and whistling, but almost always audible throughout the whole act of expiration. Crepitation may be present, especially at the bases of the lungs. The vocal resonance and vocal fremitus are not, as a rule, altered. Rhonchal fremitus may be felt when there is much mucus of an adhesive kind retained in the larger bronchi.

The main point of importance in the *diagnosis* of this variety of bronchitis is that the physical signs, as a rule, are equally distributed over both lungs. Bronchitis and emphysema are frequently present in association with quiescent or arrested phthisis, notwithstanding a prevalent opinion to the contrary; but the physical signs of those conditions will then usually be limited to a smaller area, and there may be other signs to indicate the real nature of the case, but these are often masked by the emphysema, and the phthisis is apt to be overlooked. The possibility of this complication should always be borne in mind in the case of spare individuals suffering from emphysema and bronchitis. Bronchitis complicated by collapse of lung is indicated by the general symptoms of the simple form of the disease, coupled with a more marked degree of cyanosis indicating the permanent want of a larger oxygenating surface (*see* ATELECTASIS).

Dilatation of tubes is present to a greater or less extent in almost every case of chronic bronchitis. Constant dyspnœa of long standing, paroxysmal cough, followed by the expectoration of large quantities of thick and often purulent and fœtid sputa, are the characteristic symptoms of this condition (*see* BRONCHIECTASIS). The subjects of chronic bronchitis and emphysema almost invariably become liable to attacks of spasmodic dyspnœa (bronchial asthma), which occur most commonly in the early morning about 4 A.M., or on waking from the first sleep; or

may be induced at any time by some of the various causes which give rise to attacks in cases of asthma. In such cases it is probable that a "nervous" factor has been added to the organic changes already present. During the attack the dyspnoea becomes for the time urgent, and the condition resembles that of asthma. Relief ensues when free expectoration is established.

Excessive secretion of sputa is a feature of some forms of bronchitis, especially in old and infirm subjects. Its character varies in different cases, being sometimes thin and watery, and at others thick and gluey in consistence.

Secondary changes commonly occur in the heart and other organs as the result of emphysema and chronic bronchitis, and are of great importance in determining the treatment and guiding the prognosis of each case.

Hypertrophy, followed by dilatation of the right cavities, tricuspid incompetence, congestion of the liver (nutmeg liver) and kidneys, with albuminuria and dropsy, is a sequence of events frequently observed.

The *post-mortem appearances* in all forms of bronchitis have much in common, especially as regards the condition of the lining membrane of the tubes. This is generally of a purplish-grey colour, from the greater prominence of the white elastic fibres of the inner coats of the bronchial wall. When examined microscopically, it is found to have lost almost all its columnar epithelium, a few small, bud-like projections from the basement membrane alone remaining in its place. The cellular tissue beneath the basement membrane is infiltrated to a greater or less degree with inflammatory cells, the muscular and glandular tissue being, in some cases, entirely destroyed. This cellular infiltration is limited by the basement membrane, and hence the muco-purulent contents of the tubes must be derived from the smaller bronchi, which are less seriously altered. The denuded membrane never becomes a granulating surface. Ulceration or even necrosis may occasionally be met with, but it will generally be found limited to small areas, where, from the irritation of retained and perhaps decomposing secretions, a definite local sore has been produced. The smaller tubes are almost invariably somewhat dilated. If emphysema be present, the lungs will in addition present the appearances typical of that disease.

Treatment.—The patient must avoid

as much as possible all exposure to chill and draughts, and warm woollen clothing should always be worn. When no special symptoms are present, perchloride of iron with spirits of chloroform is of service in improving the general health and nutrition of the lungs, and cod-liver oil is of almost as much value in chronic bronchitis as in phthisis.

If the cough be of such an irritating kind as to prevent rest, relief may be obtained by the use of soothing balsamic inhalations, or by means of opium or belladonna. A morphine and ipecacuanha lozenge, or one containing extract of liquorice grs. iij, oil of aniseed half a drop, with pulv. acacia and sugar, often gives much relief. Expectorants given by the mouth are, as a rule, of very little use in checking cough, but stimulants, such as ammonium carbonate and ether, are often effective, especially when the attack comes on at night. Sometimes an irritating cough may be coupled with a tickling sensation in the larynx, and is then generally due to hyperæmia or slight inflammation of the vocal cords. Such a condition is best treated by the direct application to the larynx of a solution of sulphate of zinc (20 grains to the ounce) by means of a brush.

Occasionally, where the cough is accompanied by pain or a sense of oppression in the front of the chest, counter-irritation to the sternum or even the interscapular region will often give relief. For this purpose a liniment containing 6 drachms of liniment. terebinthinae with 2 of tincture of iodine may be used night and morning, or a mustard and linseed poultice may be applied.

Of the many expectorant remedies the best are ipecacuan, squill, and senega, the balsamic preparations of benzoin, and syrup of tolu. Small doses of cod-liver oil have also a marked expectorant action. The salts of ammonia are of great service when there is much depression of strength. Local medication by means of simple or medicated steam inhalations is often of more immediate benefit than any general treatment. The action of steam alone is occasionally sufficient to loosen the adhesive mucus in the larger tubes and so to aid its expulsion, but the addition of one teaspoonful of tincture of benzoin to a pint of boiling water is usually an advantage. A draught containing sodium bicarb. grs. x, sodium chlor. grs. iij, ammonium carb. and potassium iodid. ãã grs. iij, sp. chlorof. $\mathfrak{m}\mathfrak{v}$, and aq. anisum ad $\mathfrak{z}\mathfrak{j}$, given in an equal quantity of warm water

before rising in the morning, will often, by assisting expectoration, prevent the vomiting which frequently occurs after long attacks of morning cough. If the amount of mucus in the smaller tubes be excessive, and neither expectorant drugs nor inhalations effect its expulsion, an emetic of sulphate of zinc (grs. xx-xxx) may be tried, but emetics, especially ipecacuan and apomorphia, must be used with a careful regard to the patient's strength, owing to the depression which they are liable to produce. Turpentine is often of great value in diminishing profuse expectoration. Change of air under like circumstances often succeeds when drugs fail to relieve.

If there be any gouty factor in the case, iodide or bicarbonate of potassium with colchicum should be added to any expectorant mixture which may be prescribed, and a saline purge administered.

In severe cases, and especially such as are subject to attacks of spasmodic dyspnoea, iodide of potassium grs. v-viij with ext. of stramonium gr. $\frac{1}{4}$, ext. of liquorice grs. ij, sp. chlorof. $\mathfrak{m}\mathfrak{v}$, in an ounce of water, is often of great service; the dose of iodide may be gradually increased to 15 or 20 grains. Bronchial asthma requires a treatment very similar to that described under ASTHMA, except that morphine injections are generally inadmissible. The antispasmodic powders containing stramonium often give great relief. Ether and carbonate of ammonia are also very useful, and strychnine is sometimes of considerable service.

With much venous engorgement and orthopnoea no hesitation need be felt in abstracting blood freely from the arm. In such conditions venesection, followed by the administration of digitalis, often gives the greatest relief, and may form the starting-point of a recuperative process by allowing the heart and lungs a period of rest from over-strain.

The great majority of persons suffering from bronchitis are not in a position to select their own place of residence, and their treatment is frequently hampered in this country by the most adverse climatic conditions. No part of the world is altogether free from cases of inflammation of the air passages, but they are less frequent in those regions where the range of temperature and the degree of moisture are not subject to any great or sudden diurnal variation, and, provided this condition is observed, the actual degree of heat is of minor importance. Of all atmospheric conditions, that of

cold damp is the most trying to sufferers from chronic bronchitis (*see* CLIMATE). The most suitable climates are those of islands and of the sea-coasts with a southern aspect. In England, Torquay, Ventnor, and Falmouth are the best winter climates, but they are much inferior to Madeira and the Canaries, Ajaccio, Palermo, or Corfu. For the advanced cases of bronchitis and emphysema the climate of Egypt is preferable. The Riviera is less suitable for cases of bronchitis, owing to the rapid changes of weather there and to the sudden fall of temperature which occurs in the evening hours.

E. CLIFFORD BEALE.

BRONCHITIS, PLASTIC.—A disease of rare occurrence characterized by the formation of a fibrinous membrane within the bronchi.

The *symptoms* are usually ill-defined, and a correct diagnosis is rarely possible until portions of the membrane have been expectorated. In its early stage the disease may simulate an ordinary attack of bronchitis; subsequently, there is severe cough and dyspnoea, only relieved by the expectoration of a cast of one of the tubes, and generally recurring during the formation of another. These attacks of dyspnoea most commonly occur at night. The affection may be limited to a single bronchus, as is proved by the exact similarity of successive portions of expectorated membrane. The casts are hollow, yellowish-white in colour, and vary from 1 or 2 to 6 or 7 inches in length. They are formed of fibrin, entangling in its meshes numerous leucocytes, and occasionally also red corpuscles and fat globules.

The *prognosis* is usually favourable, but death may occur from asphyxia either suddenly during an attempt to expectorate a cast, or slowly from wide extension of the morbid process throughout the bronchi.

Nothing is known for certain as to the *pathology* of the disease. The epithelial lining of the affected tubes is destroyed, but beyond this the morbid appearances are not characteristic.

Ætiology.—The disease occurs most often in males between the ages of ten and thirty, but has been observed in a child of five years and in a man of seventy. Not infrequently two or more members of the same family have been attacked. It may last a few days or two or three weeks, and in rare cases casts

have been expectorated at intervals for years. After apparent recovery the exudation may reappear.

The only *treatment* of much service is the inhalation of a spray of lime-water. Emetics have been useful in some cases; mercury and iodide of potassium are also reported to have given good results.

E. CLIFFORD BEALE.

BRONCHO-PNEUMONIA (Catarrhal Pneumonia).—This disease is most common in children, the inflammation of the pulmonary alveoli being as a rule secondary to that of the bronchial tubes. It is rarely met with in adults, but may occur in extreme old age. Three distinct forms of the affection may be recognized—(1) Simple acute inflammation, spreading downwards, as the result of a severe bronchial catarrh. This form usually runs an acute course, is attended with considerable danger, but in favourable cases is followed by complete recovery of the lung.

(2) Broncho-pneumonia may be secondary to some precedent disease of the lungs, as whooping-cough, or to some general febrile infective disease, such as measles, scarlet fever, small-pox, &c. In this variety the progress of the disease is slower and more insidious, and recovery is often long delayed, some permanent changes being not unfrequently left, such as pleuritic adhesions, or dilatation of bronchial tubes or lobular collapse.

(3) There is also a suppurative form, very rarely met with, which leads to the formation of scattered abscesses throughout the lungs. Cases of this kind are generally traceable to some direct local irritation, as the inhalation of septic material or prolonged immersion in dirty water, &c., and almost invariably have a fatal termination.

Localized inflammation of tracts of lung tissue, generally near the surface, leading rapidly to the formation of abscesses, is not uncommonly present in pyæmia, and will be found described under PYÆMIA, but it is distinct from the rare condition just referred to, which is due to actual inhalation of septic material.

Symptoms.—The onset of the disease is usually marked by an increase of fever and general illness in a child who has already been suffering for a few days from a simple catarrh or from bronchitis, or it may be more sudden, being preceded only by indefinite malaise or loss of appetite. The patient becomes very

feverish, the temperature sometimes rising as high as 104° , the pulse is rapid, the breathing is at first somewhat laboured, and this increases later on to considerable dyspnœa, which may at intervals be paroxysmal. The *alæ nasi* are generally dilated with each inspiration. The amount of dyspnœa will depend in some measure upon the degree of atelectasis which may have already taken place in the lung.

The range of temperature is very uncertain, and defervescence is usually slow, with irregular intermissions. A sudden fall of temperature is not uncommonly observed, but may be speedily followed by a rise, indicating either a fresh extension of the inflammation or the onset of acute pleuritis or empyema. There is much restlessness as a rule, and occasionally convulsion, and in some cases marked cerebral symptoms are present, which closely resemble those of tubercular meningitis. The cough is often slight at first, but increases after the more active inflammatory symptoms have passed off. There is in the case of adults rarely much expectoration except in the later stages; in young children it is of course absent. The tongue is generally coated and the bowels irregular, diarrhœa often coming on at intervals. The urine is scanty, and sometimes slightly albuminous. As the disease progresses, strength is rapidly undermined, and pallor and often a slight degree of lividity appears; the inspiratory effort becomes feeble, and causes a recession of the intercostal spaces and of the soft tissues above and below the sternum, and a suffocative condition may be set up which may terminate fatally. In the majority of cases, however, the disease is arrested before these graver symptoms appear. Recovery, in the simple form, is then steady and complete. Appetite returns, and all febrile symptoms disappear. Relapses are apt to take place if due caution be not observed, the lungs apparently remaining very susceptible to fresh catarrhal affections for some time after the original attack has passed away. Pleurisy or even empyema may thus occur.

In that form of the disease secondary to whooping-cough or the infective fevers the symptoms resemble the foregoing, but are neither so well marked nor so severe. The onset is slower, the amount of fever is generally less, and the course of the disease much more prolonged; recovery taking place very slowly, and often leaving behind a chronic cough,

with indications of the presence of permanent changes in the lungs.

The symptoms attending the rare cases in which a condition of diffuse suppuration is set up are acute at an early stage, and resemble those of capillary bronchitis. There is usually more or less cyanosis, marked anxiety of expression, sweating, and cough, with a varying amount of purulent expectoration. The physical signs are those of diminished breath sounds over a very large area, if not the whole of both lungs, with small and medium crackling râles equally widely distributed. These cases are of rare occurrence, and are invariably fatal. The history of the attack generally explains the cause. A condition of diffuse general lobular suppuration somewhat resembling cases of this nature is sometimes seen as a result of rapid disintegration of a widespread deposit of tubercle.

In each form of the disease the *physical signs* vary much in different individuals. Lobules or groups of lobules may become inflamed, and the disease may extend in patches scattered over both lungs, and show no tendency to remain limited to definite areas, although beginning, as a rule, about the bases. The inflammatory process is in each case accompanied by a varying degree of congestion, and sometimes of œdema of the surrounding lobules.

The physical signs of the simple form are not always obvious. The whole of both lungs should therefore be carefully searched in any suspected case. At one spot the inspiratory sound may be feeble, with slightly prolonged expiration and increased vocal resonance, whilst at another the breathing will be found harsh or bronchial. These signs are subject to frequent variation, and may occur at any part of either lung.

Small or medium crackling râles, with occasional rhonchi, may be audible, but these latter sounds, being dependent upon the amount of bronchitis present, are by no means constant.

Pleuritic friction sounds may sometimes be detected, and are apt to appear and disappear in any given area with remarkable suddenness.

The *course* of broncho-pneumonia is generally chronic, except in the primary simple cases, and even after recovery is apparently complete a tendency to pulmonary inflammation may remain. This chronic course is especially marked in children of enfeebled constitution, in whom permanent structural changes,

such as atelectasis, pleuritic adhesion, dilatation of tubes, or fibrosis, may result, to be followed possibly by pulmonary tuberculosis. When large areas of lung tissue are consolidated in broncho-pneumonia, resolution takes place much less perfectly than in croupous pneumonia; instead of resolution, softening and disintegration may follow, and lead to the formation of a cavity, but whether such a change ever occurs independently of tubercle may be considered doubtful.

Prognosis.—The prognosis of broncho-pneumonia at all ages must be given with caution. The mortality in infancy is very high, some statistics even showing that two-thirds of the cases end fatally. The younger the patient, and especially if below the age of three years, the greater is the risk. Rickety children, or those who are extremely fat and flabby, are the most liable to succumb. Amongst old persons the chance of recovery is in direct proportion to the general vigour of the patient; the strongest recover, but those in whom the constitution is weak and enfeebled generally succumb.

Pathology and Morbid Anatomy.—In the majority of cases the inflammation of the bronchial tubes precedes that of the alveoli; the swelling of the lining membrane of the tubules leads to narrowing of their calibre and congestion of the vesicles to which they lead. These in their turn become filled with serum, fibrin, epithelial, and inflammatory cells, a condition followed by active inflammation of their walls, which spreads to surrounding lobules or group of lobules. The result is that a small patch of consolidation is formed, which appears on section as a slightly raised, reddish, grey mass, with a dull or even granular surface. Such patches vary much in size, and a whole lobe may sometimes be studded with them; the interlobular divisions, however, remain well marked, by which the condition may be distinguished from that of acute (croupous) pneumonia.

The subsequent course of this inflammatory process depends chiefly upon the nature of the disease of which it has become a part. If the inflammation be of a simple character, resolution may take place, and re-expansion of the collapsed lung is possible. If, on the other hand, any septic or specific element is present, the solid lobules and patches are very likely to become softened and disintegrated, forming larger or smaller cavities in relation with dilated bronchial tubes. Such cavities, however, usually

shrink to very small proportions. In some instances neither complete disintegration nor complete absorption takes place, the consolidated tissue becoming the seat of fibroid changes which may lead to shrinking and obliteration of the affected lobules, with emphysema and bronchiectasis in neighbouring areas.

Cases are sometimes met with in which recent tubercular lesions are found in association with these chronic changes, which were probably the result of a previous attack of broncho-pneumonia.

Ætiology.—Simple acute broncho-pneumonia is common during the first four years of life. Rickety children, and those whose general nutrition is, from any cause, imperfect, are particularly liable to it, and this liability is rather increased than diminished by each attack.

Treatment.—This must be conducted on the same lines as those indicated for acute bronchitis. The patient should be kept in bed, and disturbed as little as possible, and the air of the room should be maintained at an even temperature of about 62°, and kept moist by means of steam. Cold draughts must be carefully guarded against. A warm flannel jacket should be worn, as the restlessness will often lead the patient to throw off the bed-clothes. The whole chest should be kept warm and moist by the continued use of poultices or hot flannel or spongipiline. In the case of a child a purge of castor oil, best administered in the form of castor-oil jelly, may be given at first, and repeated every three or four days if there be need for it. A saline draught of citrate of potash (grs. v–xv), sp. ammon. aromat. (℥iij–x), liq. ammon. acetat. (℥xx–lx), may be given, and Dover's powder in doses of grs. ½ to grs. iij, according to age, is often useful to obtain quiet sleep and allay pain. When the skin acts freely and the more acute symptoms begin to subside, expectorants, vin. ipecac. ℥iij–x, syr. tolu ℥xx–xl, sp. ammon. aromat. ℥iij–x, or ammon. carb. grs. ½–ij, may be substituted. In cases of much exhaustion with a rapid pulse, brandy (½ oz. to 1 oz.) in divided doses in the twenty-four hours is of great service. Cold baths or cold packing for the reduction of temperature are not advisable as a rule, but in cases of hyperpyrexia a careful sponging of the face, limbs, and body with water of a temperature of 80° may be tried. If much cyanosis be present, a few minutes in a hot bath containing a little mustard, cold water being at the same time poured over the head and upper part of the

chest in the case of children, often gives great relief. If there be much venous congestion, a venesection to 3 oz. will often prove beneficial. In the later stages, if the larger tubes become clogged with mucus, urgent dyspnoea and cyanosis result. An emetic dose of ipecacuan wine (ʒij to vj) is the simplest remedy for this condition. The diet should be restricted to milk and farinaceous foods, administered in small quantities at short intervals. Thirst may be relieved by sips of water acidulated with a few drops of dilute hydrochloric acid. It may occasionally be necessary to feed by means of small nutrient enemata, and in the most difficult cases it is advisable to resort to these in preference to the nasal tube or other mechanical means of introducing food into the stomach.

In cases of broncho-pneumonia occurring in persons of advanced age the amount of rest that is obtained, and the quantity of food that is taken, are important factors in determining the result. Strict rest in bed must be insisted upon, the patient not being allowed to rise for any purpose whatever. Milk, nutritious jellies, or peptonized foods should be given in small quantities at least every two hours. Stimulants in the form of brandy or whisky are generally called for, and must be used with freedom if necessary. A close watch must be kept upon the heart's action, and any indications of failure combated by digitalis or strophanthus in doses of 5 to 10 minims of the tincture, and by diffusible stimulants, such as carbonate of ammonia (grs. v–x) and spiritus ætheris (℥xv–xxx). The bowels in old persons need not be urged unless there be actual discomfort arising from the constipation. A simple enema is then the appropriate means of relief.

Poultices should be kept applied to the affected side or to both sides of the chest if necessary, and should be changed every four hours, care being taken to disturb the patient as little as possible in the process. Sponging of the hands, arms, and face may be done twice in the day for cleanliness and its refreshing effect.

Great care must be exercised to prevent recurrence during the period of convalescence. It is particularly apt to take place, and with each relapse the inflammation becomes more chronic and intractable. Change of air is generally advisable after the attack has subsided. The bracing shores of the Eastern

counties are most suitable to the younger patients during the summer months, but the Southern and Western coasts of Devonshire, Cornwall, or Wales, or the Isle of Wight should be selected during the cold season for young and old alike.

E. CLIFFORD BEALE.

BROW AGUE is neuralgia of the first division of the fifth cranial nerve. It is so called because the affection is common in malarious districts, and it then presents an intermittent character, the attacks coming on at regular intervals in a similar manner to those of ordinary ague. It may, however, occur independently of any malarious influence, when it is probably dependent upon some diathesis—*e.g.*, gout—the attacks being apparently induced by chill. Or it may be symptomatic of some cancerous or other affection of the bones of the skull in the immediate neighbourhood. When not dependent upon malaria, the treatment would be the same as for other forms of neuralgia (*q.v.*).

BULBAR PARALYSIS (**Labio-Glosso-Laryngeal Paralysis**) is a disease of the motor nuclei in the medulla oblongata.

The disease occurs in an acute and also in a chronic form. The latter only, which is most commonly met with, will be here described.

Two other forms of bulbar paralysis are described—the “apoplectiform,” which comes on suddenly, and is due to a lesion in the fibres descending from the cortex to the bulbar nuclei, and the “acute inflammatory,” analogous to acute poliomyelitis. These are of such rare occurrence as only to require mention.

The *symptoms* begin very insidiously, and take the form of a progressive bilateral atrophy of the muscles of the tongue, lips, soft palate, and pharynx, with consequent paralysis of these parts. The tongue is usually the first to be affected, and, before there is any wasting of this organ, the patient has a difficulty in uttering dentals and linguals. The appearance of the tongue is quite characteristic: it is atrophied, the mucous membrane is thrown into folds, like a half-empty bag, while, at the same time, numerous fibrillar twitchings are seen on its surface. The lips become weak from wasting of the orbicularis oris, so that the patient cannot purse up the mouth or pronounce explosive labials. The soft palate becomes paralysed, usually bilaterally, the patient being un-

able to close the posterior nares. This is best tested by making the patient blow up his cheeks whilst the anterior nares are nipped by the fingers; then, on suddenly removing the pressure, the air rushes through the posterior nares from the mouth.

The speech acquires a nasal tone, and the word “rub” becomes “mrum.” In most cases the soft palate loses its reflex action to the stimulus of tickling.

As the case advances the patient gets a characteristic mournful expression—though most patients are really exceptionally cheerful and good-tempered—the lower lip drops, the saliva is not swallowed, but dribbles continually out of the corners of the mouth, or hangs in ropy festoons about the fauces; the tongue cannot be protruded from the mouth, speech is lost, and only a grunting sound can be made. Swallowing is difficult, owing to regurgitation into the nose or the larynx, the muscles of which are now paralysed. The epiglottis cannot be raised, and the vocal cords cannot be approximated. The wasted muscles of the tongue respond to the Faradic current as long as there are any fibres left, but with the constant current they give the reaction of degeneration—*i.e.*, react to the positive better than the negative pole, and give a slower contraction than in health. Bulbar paralysis is frequently associated with progressive muscular atrophy and with amyotrophic lateral sclerosis, and in the latter condition clonus of the lower jaw is frequently obtained.

Course.—The disease runs a slow progressive course, and usually ends fatally in from one to four years, death resulting either from inanition, impaction of food in the glottis, bronchitis or pneumonia set up by particles of food which have got into the lungs, or from direct implication of the respiratory and cardiac centres in the medulla oblongata.

The *pathology* is similar to that of progressive muscular atrophy, and consists of gradual atrophy of the motor nuclei of the medulla, especially the hypoglossal, the spinal accessory (which supplies the levator palati), also less frequently of the nuclei of the vagus, glosso-pharyngeus, the facial and the motor division of the fifth nerve. The cells of these nuclei atrophy, and lose their processes, granule-corpuscles appear in the interstitial tissue, and in some cases the anterior pyramids are degenerated. The muscles supplied by the atrophied nuclei waste and undergo fatty and granular changes,

while the nerves supplying them are grey, from degeneration of nerve fibres and increased interstitial tissue.

The *diagnosis* of the disease does not, as a rule, present much difficulty, the gradual bilateral wasting of the muscles being its chief characteristic. It has to be distinguished from acute bulbar paralysis, which has a sudden onset; and from lesions of the cranial nerves outside the medulla, secondary to tumour or syphilitic disease. In the latter cases there is more pain, and the symptoms are not usually bilateral. There are also more distinct changes in the electrical reactions. Intra-medullary tumours often involve other nuclei, as that of the facial or sixth nerve, and other signs characteristic of a tumour will be present.

Etiology.—Bulbar paralysis is a disease of advanced life, rarely beginning before forty, and occurring in cases with an hereditary neurotic history. The causes given are exposure to damp and cold, mental anxiety, and bad living, but in a certain number of cases no cause

can be ascertained. Syphilis is not a predisposing cause.

The *treatment* of the disease is very unsatisfactory. The general health may be improved by the administration of nervine tonics, such as arsenic, phosphorus, quinine, and strychnine, and by cod-liver oil. Temporary improvement has been obtained by hypodermic injections of strychnine (gr. $\frac{1}{60}$), with small doses of morphine (gr. $\frac{1}{30}$ to $\frac{1}{24}$), but the improvement has not been permanent (Gowers). With regard to electrical treatment, the writer has never seen any definite good result from its use, but, as he has seen marked improvement in early cases of progressive muscular atrophy, a trial should certainly be given to the constant current, the positive pole being applied to the back of the neck, and the negative pole to the affected muscles, so as to produce a slight contraction.

Great care must be taken in feeding these cases; semi-fluids answer best, but in some cases œsophageal tubes or catheters have to be used.

C. E. BEEVOR.

C

CACHEXIA is the name given to the state resulting from the prolonged duration of certain diseases, and especially of those associated with impoverishment of the blood. The principal signs are an earthy, muddy, sallow, or pallid complexion, according to the disease which has induced it, and some degree of emaciation. Syphilis, malaria, cancer, tubercle, disease of the spleen, chronic diarrhoea, and rickets are the most common causes of cachexia. Some writers speak of a cancerous cachexia or a tubercular cachexia; used in this sense, the word cachexia would be synonymous with diathesis.

CANCER ORIS (Gangrenous Stomatitis; Noma; Gangrenous Ulceration of the Mouth).—*Symptoms.*—

As the disease is frequently unattended with pain, it may often have made much progress before it is discovered. Usually, the first thing that is noticed is a brawny swelling in the substance of the cheek; this softens and breaks down, and ulceration occurs on the inner aspect of the cheek; in very exceptional cases it may commence on the outer surface. The breath becomes horribly fœtid, there is a

sanious discharge, a sloughing ulcer is seen in the cheek, which may even be perforated, and there is enlargement of the lymphatic glands.

In spite of the severity of the local mischief, the child apparently suffers little pain and takes food readily. Symptoms of great prostration soon set in, the pulse becomes very rapid and almost imperceptible, and the patient dies from exhaustion or blood poisoning.

Diagnosis.—The appearances are so characteristic that the diagnosis is readily made.

The *prognosis* is almost absolutely unfavourable.

Pathology.—By Hutchinson the disease is regarded as allied to, or identical with, hospital gangrene and syphilitic phagedæna. In severe cases the gangrene, after perforating the cheek, may spread in all directions, involving lips, tongue, alæ nasi, and eyelids, and causing exfoliation of the teeth and of portions of the jaw.

Etiology.—Cancer oris is chiefly met with in children between the ages of one and five, convalescing from the acute specific diseases, especially measles. The surroundings of the patient are almost invariably insanitary.

Treatment.—The only hope of cure lies in the early and free destruction of the gangrenous surface with fuming nitric acid, the patient being anæsthetized. The use of antiseptic lotions for the mouth, and the administration of chlorate of potassium, tonics, and stimulants may subsequently be of service.

F. DE HAVILLAND HALL.

CANITIES (Poliosis), or greyness of the hair, is an acquired condition caused generally by the gradual cessation of formation of the natural pigment, or, exceptionally, by the sudden disappearance of existing pigment. Senile canities is almost a physiological process; it usually begins in the temporal region or in the beard.

Premature canities is frequently hereditary; it may result from neuralgia, worry, or overwork, may complicate alopecia areata and leucoderma, or may follow acute diseases, especially scarlatina. In summer the follicles may resume their pigment-producing function to some extent, and complete recovery occasionally takes place. In exceptional cases the hairs are "ringed"—i.e., present alternate coloured and colourless zones.

Under the influence of strong emotion, especially fear, sudden whiteness of the hair may show itself within a few hours, due either to great increase of the quantity of air normally present in the hair-shaft, or to some sudden change in the constitution of the sweat, giving it an extraordinary bleaching power. There is no cogent evidence, however, in support of the latter theory.

The only *treatment* consists in the use of suitable dyes; those containing a solution of nitrate of silver, followed by sulphur, to give a light colour, or by pyrogallol acid, to give a darker tint, are probably harmless.

J. J. PRINGLE.

CANTHARIDES, Poisoning by.—The *symptoms* are those of an active irritant poison; burning in the mouth and a sense of constriction in the throat are noticed at once, followed by pain in the epigastrium, great thirst, difficulty in swallowing, salivation, vomiting, and the passage of blood in the stools. Pain in the loins, frequent calls to micturate, and violent tenesmus of the bladder (*strangury*), are prominent symptoms following upon the absorption of the poison. The urine may contain blood, or the secretion may be sup-

pressed. Swelling of the genitals (priapism) in the male, and in pregnant women a tendency to abort, are symptoms occasionally present. Conjunctivitis, lachrymation, and blisters in the mouth have been noticed in some cases. Death may take place from coma or convulsions.

Post-mortem Appearances.—The powder may be found adhering to the mucous membrane of the stomach, and may be recognized by its glistening appearance; there will be intense inflammation throughout the whole or part of the alimentary canal, and the kidneys and bladder will also be inflamed.

Treatment.—The indication is to get the poison out of the body as speedily as possible; the stomach must be washed out thoroughly if an instrument for the purpose be at hand; if not, an emetic of sulphate of zinc (grs. xxx, in water) or mustard (a table-spoonful of the powder in water) should be administered. Barley-water, white of egg and water, or linseed tea, may be given freely, but oil should be avoided. Opium or morphine is of great service, and stimulants may be necessary.

CARBOLIC ACID, Poisoning by.

—*Symptoms.*—A burning and disagreeable taste in the mouth, vomiting, cold perspiration, small pulse, and faintness are amongst the early symptoms. The pupils become contracted and insensible to light, the breathing shallow, and the patient loses consciousness. Convulsive twitchings and a lowering of the temperature are often present. The urine is of a deep olive-green colour, turning black on keeping, and having no tendency to decomposition. Death, when it occurs, takes place rapidly, and is due to failure of respiration.

Post-mortem Appearances.—The mucous membrane of the mouth, throat, and gullet will be white, sodden, and sometimes eroded; there will be brownish stains about the mouth; the mucous membrane of the stomach, and to a less extent of the small intestine, may be thickened and corrugated; the bronchi will be inflamed, and the lungs somewhat congested. The vessels of the brain, the right side of the heart, the liver, spleen, and kidneys will be congested. All the viscera will smell of the poison, and putrefaction will be delayed.

Treatment.—The stomach should be thoroughly washed out with soda or saccharated lime dissolved in large quantities of tepid water until the fluid

returned is free from odour, or nearly so. A solution of Glauber's salts or Epsom salts may then be left in the stomach. Olive oil and white of egg may be given freely; stimulants and warmth externally will probably be required. If there be a marked degree of coma, the treatment should be as in narcotic poisoning.

CARMINATIVES are used to relieve griping pain, the result of flatulent distension of the stomach or intestines, or to prevent the pain which may arise from the administration of certain purgatives. The chief are the essential aromatic oils, ether, camphor, chloroform, ammoniacum, and the aromatic bitters. Such remedies are generally most efficacious when given in moderate doses and at short intervals.

CARPHOLOGY.—A condition characterised by plucking at the bed-clothes, and other movements of the hands, occurring in the delirium which often accompanies the later stages of febrile affections. It is generally regarded as an unfavourable symptom. The term "flocitatio" was formerly used to describe the same condition.

CARPO-PEDAL CONTRACTIONS.—A condition met with in young infants. The fists are clenched, the thumbs being bent on the palms and covered by the fingers; the toes are flexed, and the feet arched. There is also flexion of the elbows and knees. This condition may be taken as an indication of a tendency to convulsions, and is not infrequently associated with dentition or the presence of thread-worms. Another variety will be found described under the head of TETANY.

CASTS, URINARY.—This term is applied to cylindrical bodies having the appearances of moulds of the renal tubes. When present in large numbers, they form, on standing, a small deposit visible to the naked eye. To find them, this deposit must be very carefully examined (*vide URINE, EXAMINATION OF*). The addition of a little staining fluid, such as osmic acid or fuchsin, will render the paler varieties more distinct. Oblique illumination should be employed.

CHARACTERS.—Casts vary considerably in size, shape, and general appearance. In *length* they range from a mere fragment to 200 μ or more; in *diameter* from 4 μ to 40 μ ($\mu = \frac{1}{1000}$ millimeter =

$\frac{1}{250000}$ inch; diameter of red blood disc = 7.5μ). The large majority fall into one of two groups—(1) those of 10 to 15μ diameter, called “small,” and (2) those of 25 to 40μ , called “large.” In *shape* they are generally straight or slightly curved cylinders, but sometimes much twisted, convoluted, or fissured. As a rule there is a fractured surface at each end, but occasionally these are round, or, much more rarely, tapering. The outline is for the most part distinct and sharp, but has more of the highly refracting characters of a vegetable fibre.

The more characteristic appearances, and hence the names, vary according to the tissues embedded in the mould or cast, which essentially consists of a homogeneous, almost invisible matrix. Thus there are *epithelial* casts (Figs. 1 and 4), containing scattered patches of more or less altered renal epithelium; *blood* casts (Figs. 1 and 2), with red blood discs in their interior; *pus* casts (Fig. 2), studded with degenerate leucocytes; *fatty* casts (Fig. 3), with fat globules singly or in groups; *granular* casts (Figs. 1 and 4), with finely divided granular debris either in scattered masses or completely filling the cast; *hyaline* casts (Fig. 2), clear and transparent, with a few lateral fissures, but homogeneous in structure. Others are named according to the belief held concerning their origin—*e.g.*, *waxy* casts, which give the albuminoid reaction, and *mucous* casts, probably made up of mucus.

MODE OF FORMATION.—The diameter of a cast depends on that of the tube in which it is formed. Not only does this vary within wide limits in different parts of the cortex and pyramids, but it may be indefinitely increased by loss of the epithelial lining or by dilatation of

FIG. 4.*

a, Epithelial casts. b, Granular casts.

the tubes themselves. The convoluted tubes were originally supposed to be the chief sites of cast formation from the shape of the casts, because blood and pus cells would be more readily accessible in the neighbourhood of the glomeruli, also from the fact that fatty degeneration of the epithelium had not been observed elsewhere, and, because, after death, casts were found as plentifully in the convoluted as in the collecting tubes.

But to escape from the convoluted tubes the casts would have to pass through others whose diameters are much smaller either than those of the tubes in which they were supposed to be formed or than those of most of the casts themselves as seen in the urine. Now many writers, while admitting their pliability, doubt their power of accomplishing this feat, and are therefore of opinion that they really originate in the

* The above drawings are from Dr. Beale's work on “Urinary Deposits.”

loops of Henle and in the terminal tubes, but never in the convoluted.

It must be remembered, however, on the other hand, that the cast may gain in consistence as it passes along the tubes and during its sojourn in the bladder, and therefore that at the time in question it may be sufficiently compressible to traverse the smaller tubes.

Branched casts, which are rare, are believed to be formed in the collecting tubes, and mucous casts in the folds of mucous membrane present in the membranous part of the urethra. Mucous casts occasionally contain spermatozoa. The seat of origin of the other varieties must be considered as undecided.

The nature of the process of cast formation is not more clearly understood than the site. The essential part of the cast is the matrix, and four theories are advanced to account for its origin. According to one it is fibrin; to another, one of the products of disintegrated epithelium; to a third, an exudation from the inflamed epithelium; and to a fourth, an albuminous exudation, possibly the result of an inflammatory process which tends to detach the epithelium from the sides of the tubes.

There is certainly no reason why the matrix should in all cases be similar, and there can be but little doubt that the majority of casts result from an inflammatory process, as they occur in greatest quantity in active inflammatory conditions, and their number is often directly proportional to the amount of albumen present in the urine. The clear transparent matrix may be partly due to the action of the acid urine on the coagulated fibrinogen. It is impossible to say in what proportions exudation from the blood-vessels and the products of disintegrated epithelium enter into its formation. The epithelium in casts is generally very much altered. It is probable that some blood casts are simple coagula, and composed, therefore, of fibrin and corpuscles; but this explanation does not seem probable where two or three blood discs are scattered through a cast of considerable size. That the matrix may be simply an epithelial exudation is affirmed by those who have observed the casts lying by the side of epithelium from which masses of apparently similar material projected.

SIGNIFICANCE.—While so much difference of opinion exists concerning the place and mode of origin, the diagnostic significance of their presence must mainly depend upon clinical experience. This

may be thus shortly summarized:—(1) If the prevailing type of cast, be of the "blood" or "epithelial" varieties, acute nephritis, either primary or supervening on chronic disease, is the probable condition. (2) Fatty casts occur during convalescence from acute nephritis, or in cases where that condition has become chronic. Their persistence points to the latter alternative. (3) Granular casts are possible in acute disease, but are generally found in large numbers in cases of contracted kidney. (4) Blood and pus casts in cases of pyelitis show that the kidney substance is also involved. (5) Hyaline casts may be found when there is no other evidence of disease. (6) Casts are found in largest number when active inflammatory changes are taking place in the tubules—that is, in cases of acute or sub-acute nephritis.

H. MONTAGUE MURRAY.

CATALEPSY is a morbid state of the central nervous system, characterized by a condition of muscular contraction known as *flexibilitas cerea*. This is such that there is no voluntary movement and no opposition to passive movement of the limbs or body in any direction; and along with this there is a power of retaining for an indefinite time any position imposed, much longer than is found possible by voluntary effort in health. Such a condition is exceedingly rare unless accompanied by other nervous disturbance, most commonly by more or less complete anaesthesia, loss of memory, and unconsciousness. In primary cases, where catalepsy is the chief symptom of disease, its onset is rapid. It is met with in subjects of from twenty to thirty years of age, both men and women of nervous temperament, and follows emotional excitement or exhaustion. It may fix its subject motionless or speechless in the midst of action or speech, and release him only after some minutes or hours, without memory of the interval, to finish what he was engaged upon. Of any constant electrical changes in the nerves or muscles during the attack there is no satisfactory evidence, and beyond the abnormality of contraction and anaesthesia there may be little noteworthy in the physical condition during the attack; more probably there will be a weak pulse, slow breathing, and open, staring eyes. Now and then such a state has been known to last several weeks, and artificial feeding has been found possible; the temperature, however, being

reduced, the functions somewhat in abeyance, and the patient needing little nourishment. More often there are groups of less severe attacks, each lasting a few minutes, in which some periodicity may develop itself.

The cataleptic state is found, although rarely, as a symptom of importance in many diseases. It has ranked as a twin sister to hysteria, and is frequently intimately associated with its other symptoms; hystero-catalepsy may alternate with hystero-epilepsy, or hysterical chorea (Charcot); it occurs with tetanus and various forms of mania and melancholia (cataleptic torpor), though it ceases when they have degenerated into dementia. It is a grave though very rare symptom in some acute diseases, such as typhoid fever, ague, and pneumonia. It belongs to the symptoms contagious by involuntary imitation, as in the religious epidemics of the Anabaptists in 1686 and of the Calvinists of St. Médard in 1731. It often forms a part of the hypnotic state (*see* HYPNOTISM), and may then follow on gentle pressure upon the closed eyes of sensitive subjects or on suddenly exposing them to a bright light. In this way, by unilateral action or suggestion, an artificial hemi-catalepsy may be induced. By itself it has no serious consequences, but it may be very inconveniently persistent. Primary attacks often terminate in some small crisis, as epistaxis or menstruation. They can rarely be cut short by cold water, faradization, massage, or other treatment, but their recurrence may be gradually prevented by an active life, change of scene, moral stimulus, and encouragement. The pathological condition is as yet unknown.

A. T. MYERS.

CATARRH signifies inflammation of a mucous membrane with increased secretion of fluid from that membrane. The term is generally reserved, when used by itself, for catarrh of the mucous membrane of the nose, throat, and larynx, constituting what is popularly termed "a cold." It usually follows a wetting or exposure to cold of some kind, and may or may not be preceded by chilliness and vague feelings of pain or discomfort in the limbs and joints. In many persons the first symptom is dryness or soreness of the throat, followed in a few hours by sneezing and a profuse watery discharge from the nostrils. Hoarseness and lachrymation will be present in very varying degree,

being always a prominent feature of the attack in some individuals, but wholly absent in others. In the course of the second day the discharge from the nose usually becomes less abundant and more turbid, and from this time the mucopurulent character of the discharge is more marked, whilst it diminishes in quantity. Smell and taste are diminished or lost during the acute stage, the former, indeed, not being regained until the discharge has nearly ceased. Deafness is by no means uncommon, and soreness and excoriations about the lips are often seen.

Treatment.—An attack may sometimes be cut short if at the very commencement measures be taken to promote copious diaphoresis—*e.g.*, a Turkish bath—whilst a hot bath before getting into bed, or putting the feet into hot water with a little mustard in it, are well-known domestic remedies, which may be aided by drinking some hot wine or hot spirit and water. A full dose of quinine (grs. x) taken upon the approach of the first feelings of discomfort, or small doses of morphine, or 5-minim doses of the tincture of aconite every half-hour for three hours may also have the desired effect. Tincture of belladonna in 20-minim doses combined with 10-grain doses of bromide of potassium has been found serviceable, and it has also been recommended to brush the nose and pharynx three or four times with a 6 per cent. solution of cocaine. When the catarrh is established, Ferrier's snuff may be recommended; it contains morph. hydrochl. grs. ij, bism. subnit. ʒvj, and gum acacia ʒij. In chronic cases quinine in moderate doses is useful.

CAUSTICS are substances which, when applied locally to organic matter, cause its destruction. The actual cautery (a red-hot iron), Paquelin's cautery, and the galvanic-cautery are the most efficient. As chemical caustics, the hydrated oxides of potash and soda, nitrate of silver, and nitric acid are the most common, but the acid nitrate of mercury, chromic acid, chloride of zinc, chloride of antimony, and glacial acetic acid are also powerful caustics.

CHEIRO-POMPHOLYX (Dysidrosis, Pompholyx) is an ill-defined, inflammatory disorder of the skin of the hands, and often also of the feet, characterized by the development of peculiar vesicles, or blebs, arranged in groups. These are deeply seated, and have the

appearance and feel of sago-grains; they are distributed chiefly on the soles and palms, and especially along the sides of the fingers. The surrounding skin is at first little, if at all, inflamed. Blebs are usually formed by the fusion of smaller vesicles, but occasionally appear primarily. The vesicles either suppurate and rupture, causing excoriation and maceration of the skin, or more frequently are absorbed, leaving the skin unaffected. Their appearance is preceded and accompanied by violent itching, a feeling of stiffness, and burning pain. The eruption is roughly symmetrical. The disease avoids the extremes of life, and is especially common in women and persons of neurotic disposition, with clammy hands (chronic hyperidrosis). It is almost invariably recurrent, and is rare in winter. After frequent recurrence the nails become stunted and brittle. By some the vesicles are thought to represent dilated sweat ducts containing retained sweat; by others the disease is considered to be of neurotic origin, and allied to herpes. More probably it is an atypical eczema, as eczema frequently co-exists on the trunk, or is in anatomical continuity with the disease, which sometimes appears to be provoked by external irritants.

The *diagnosis* from scabies may occasionally present some slight difficulty.

Treatment must be mainly constitutional; arsenic and quinine are of special value. Locally, lead lotions, thymol in weak alcoholic solution, or diluted liquor carbonis detergens may be used to allay itching.

J. J. PRINGLE.

CHELOID (Keloid of Alibert, Kelis) is a somewhat rare disease of the skin, characterized by the development of new growth from the connective tissue. Formerly a sharp distinction was drawn between "true," *i.e.*, spontaneous, and "false," *i.e.*, cicatricial, cheloid; clinical experience, however, teaches that probably all cheloid arises from pre-existing scar-tissue or inflammatory exudation. The extensive scars resulting from burns, lupus and syphilis are specially prone to form the starting-point of cheloid, but it may originate in and spread from the minute scars following blisters, variola, varicella, acne, leech-bites, or piercing the ears for ear-rings. Less frequently the process may start from deep inflammatory changes—*e.g.*, boils. The coloured races are more often affected than whites, brunettes more often than blondes. Some families show

a marked proclivity to cheloid formation, and in some persons every scratch or scar may become affected, evidencing a peculiar constitutional taint. The disease is commonest in middle-aged people, but the cicatrices resulting from strumous ulceration in children are often markedly hypertrophic. Cheloid is commonest, and presents its most characteristic form, over the sternum; it is also common about the shoulders and neck, but may, as already indicated, occur upon any part of the body.

Symptoms.—The growth first shows itself as a firm, raised, smooth, glossy, cicatriform streak or nodule, which may be whitish, pinkish or red in colour. By its gradual increase a larger, prominent tumour is formed, elastic to the touch, and hairless; sometimes dilated venules course over its surface. From this central tumour irregular raised bands or spurs extend in various directions into the surrounding skin like the claws of a crab—hence the name of the disease. Considerable pain is usually complained of, especially when the part is manipulated, as well as itching, stinging, and burning sensations. The growth may extend indefinitely, the older portions becoming atrophic and depressed, the more recent, irregular and tuberosus; but suppuration and ulceration are of very exceptional occurrence, as is also the development of malignant growths from it. The increase of the tumours is invariably slow, and after a certain time—it may be years—spontaneous arrest usually occurs, followed by gradual diminution in size, but they seldom totally disappear. If removed, either by the knife or by caustics, they almost invariably recur *in loco*.

A rare form of cheloid is described by Mr. Hutchinson in which the new growth is confined to the deeper layers of the corium and to the subcutaneous tissue, the result being extensive flat indurations covered with healthy skin.

Pathology.—The growth originates in the corium, of which the vessels are dilated and the meshes infiltrated with numerous cells, which press upon and destroy the sebaceous glands and hair follicles, obliterate the papillæ, and rapidly form dense fibroid tissue. The fibres lie closely packed together, in bundles, in the long axis of the tumour, with a few spindle cells and nuclei among them, and in the later stages of the disease are very poorly supplied with blood-vessels. The condition is closely

allied to granuloma on one hand, to sarcoma on the other. The vessels are dilated for a considerable distance outside the growth. The condition differs clinically from simple hypertrophy of a cicatrix in its aggressive extension beyond the scar tissue; possibly the growths, when multiple, might be mistaken for fibromata or malignant tumours of the skin.

Treatment.—The application of mercurial or lead plaster appears sometimes to check cheloid growth, probably by exerting compression on the vessels. Belladonna plaster is useful in alleviating pain, and occasionally recourse must be had to morphine. Destruction by caustics is unsatisfactory; removal by the knife is only efficacious when the incisions are made very wide of the growth, and is not usually an advisable measure. Linear scarification and electrolytic puncture have been recently warmly advocated. It must be borne in mind that spontaneous arrest and partial recovery usually take place, especially in young persons.

J. J. PRINGLE.

CHEYNE-STOKES' RESPIRATION.—An undulating type of breathing in which the respirations gradually become more frequent and, at the same time, deeper, until a certain point is reached, when they slowly become more shallow and less frequent, until the person finally seems to have stopped breathing; after a pause, which may be as long as half a minute, the respiration begins again very slowly, but gradually increases in frequency and depth, and thus the cycle is established. This condition is most common in the late stages of tubercular meningitis, but it is also met with in some forms of cerebral hæmorrhage, and in fatty disease of the heart, when presumably it is due to the influence of insufficiently oxygenated blood on the medulla oblongata.

CHICKEN-POX (Varicella).—An acute and highly contagious disorder, characterized by the appearance of successive crops of vesicles. It is most common in children under four years of age, but older children are also liable to it, and in rare instances the disease also occurs in adults.

Symptoms.—The invasion may be quite sudden, or its onset may be heralded for a few hours by febrile symptoms and general malaise, but it is rare for the premonitory symptoms to last more than a few hours before the appearance

of the rash. This comes out as a rule first on the back or chest in the form of scattered, slightly raised, round, red or rose-coloured spots, which disappear when the skin of the part is stretched. In the course of a few hours each spot becomes raised, by the accumulation of serous fluid in the underlying layers of skin into a small vesicle containing an almost clear or slightly yellowish fluid. The vesicle is round or oval, tense, varies in size from a hempseed to a split-pea, and has no central depression. In the course of twenty-four or thirty-six hours the contents of the vesicle become cloudy, its apex falls in, and it gradually shrivels up, so that by the fourth day it is reduced to a mere scab, which may then crumble away leaving no trace of its existence, but, as the scabs often itch and are scratched, it is quite common for a few scars to be left here and there. On the following morning a new crop appears, generally far more numerous than the first, and not confined to the trunk, the limbs, head, and sometimes the face being attacked. As the disease advances a fresh crop of spots makes its appearance every morning for four or five days, so that by the fifth day the eruption may be studied in all its stages, from the initial red spot to the final crumbling scab. The total number of spots may vary from ten or twenty to one or two hundred or even more. A red areola is frequently seen, though it is by no means necessarily present in any stage of the vesicle. Vesicles are not infrequently seen on the palate, mucous membrane of the cheek, and sides of the tongue, and also on the labia or prepuce. It is probable that in its early stages the vesicle contains septa dividing it off into compartments, but when fully developed the septa all become absorbed, and the vesicle is then undoubtedly unilocular. The marking of the scars, however, so closely resembles what is seen in small-pox as to make it almost certain that there must have been septa in the vesicle at the time of its original formation. The temperature does not, as in variola, subside when the eruption appears, although in some cases a slight fall may occur until the evening, when it again rises. Sometimes there is no fever throughout and no feeling of ill-health.

The *period of incubation* is uncertain, but it is probably long; most writers are agreed that it may last a fortnight, if not more.

Mr. Hutchinson has described under

the name of varicella prurigo some cases in which, after undoubted chicken-pox, there has been a persistent eruption exactly like the original disease, and accompanied by much prurigo. In a few instances, generally in unhealthy and tuberculous children, the vesicles have taken on a gangrenous ulceration, and the child has succumbed. Acute tuberculosis, too, has been known to supervene so soon after chicken-pox as to suggest something more than a coincidence; organic disorders of the central nervous system have also, in rare instances, been noticed to follow an attack of chicken-pox.

As regards the *diagnosis* the chief difficulty is to distinguish between this affection and modified small-pox. If the eruption be observed to go through the successive stages above described, there is no room for doubt, but when the patient is only seen once and in the early stage, the difficulty may be very great. In small-pox there will almost always be a history of two or three days' malaise before the first appearance of the eruption, which may have been preceded by a scarlatiniform rash, and the papules will have from the first a hard, shotty feel which is never present in chicken-pox. It will often happen, however, that a certain diagnosis cannot be made on first seeing the patient.

It is unnecessary to re-open the discussion as to the identity or otherwise of small-pox and chicken-pox. Suffice it to say, that an attack of the one does not protect against the other, that vaccination affords no protection against chicken-pox, and that a person whilst suffering from chicken-pox can be successfully vaccinated.

No special *treatment* is needed, but it is prudent to keep the patient in bed whilst the eruption is developing, and to isolate him from those who have not had the disease.

JOHN ABERCROMBIE.

CHILBLAIN (*Pernio*; *Erythema Pernio*) is a local inflammation of the skin resulting from exposure to cold. The condition is occasionally observed in old persons, but is far more common in the young, especially in those of lymphatic constitution, with a tendency to suffer from "blanched fingers," "cold blue hands," and other manifestations of a weak peripheral circulation. Anæmic girls are particularly liable to the affection, and in them it occurs in the most aggravated and obstinate form. After

full development is attained, the affection is far less frequently met with.

Chilblains always appear first in winter, and generally cease spontaneously when the weather becomes warm. The hands, especially the fingers and knuckles, the margins of the feet, the heels, toes, ears, and the tip of the nose are the most favourite seats.

The lesions generally develop during the night, when the body is at rest; they consist of variously sized, single or multiple, circular, raised, erythematous spots or patches, which are at first of a delicate pink colour, but soon assume a red and subsequently a purplish hue. Itching, smarting, or burning is severe and is aggravated by warmth. If the inflammation progress, vesication occurs over the patch, and ultimately large bullæ containing clear or blood-stained serum may form. The cuticle covering the bullæ may separate and leave a denuded, sloughy surface, the most advanced stage of the affection. Recovery then takes place slowly by granulation, and shallow scars may result, comparable to those produced by erythematous lupus, with which affection, indeed, this disease has much in common. It has also many interesting points of affinity with Raynaud's disease.

Treatment.—Young persons liable to chilblains and allied conditions ought to be forced to take regular and vigorous exercise. Standing in front of a fire for considerable periods is specially likely to induce the condition. The clothing must be warm and woollen, thick gloves and stockings being worn. The boots must on no account be tight or of the kind known as "elastic sides." The sleeping chamber should be warm.

On the first appearance of the signs of chilblains, the parts should be rubbed with cold water or even snow, in order to restore the circulation gradually; afterwards rest, moderate warmth, and a little calamine lotion (3j ad 3j with glycerine) suffice to prevent their further development. If the erythematous stage be reached, tincture of iodine is useful, and for application to exposed tracts it may be decolorized by the addition of ammonia. If a little more stimulation be necessary, equal parts of the liniments of camphor and belladonna, or of turpentine and iodine, or of soap and chloroform are all efficacious, and may be followed by a lead or soap plaster. Should vesication occur, painting with compound tincture of benzoin, followed by smearing with resin ointment, answers admir-

ably. The same treatment may be applied to the bullæ after the removal of the epidermis. In other cases more soothing applications (*e.g.*, calamine or borax ointment) are preferable. Sometimes erythematous patches, which constantly threaten to "break," persist indefinitely; they are best treated by painting with a solution of nitrate of silver in spirits of nitrous ether (grs. xv ad 3j) or with liquor gutta-perchæ containing 5 per cent. of salicylic acid. Galvanism, as in Raynaud's disease, may often be used with advantage.

The constitutional treatment is of much importance; it embraces good food, hygienic surroundings, regular exercise, and the administration of tonics, especially quinine, strychnine, and iron.

J. J. PRINGLE.

CHILL.—It is difficult to assign its proper value to this term. There is probably no disease which has not justly or unjustly been attributed to taking a chill. It is often the only assignable cause of the most varied affections. A chill consists in a sensation of cold and shivering coming on within a few hours of exposure to cold or wet.

CHLOASMA (Melanoderma; Melasma) is an acquired condition characterized by the presence of smooth, pigmented patches, or a diffuse general pigmentation of the skin, the tint of which may vary from yellow to dark brown. In a few well authenticated cases diffuse pigmentation has appeared suddenly after strong mental emotion or acute disease, but in the great majority of cases the disease is secondary to disorders of the female generative organs.

Chloasma uterinum affects chiefly the forehead, temples, cheeks, the nipples, and the skin of the abdomen along the middle line. It is often very marked during pregnancy, and subsides—but only partially—after parturition; in a milder degree it may affect brunettes at the menstrual periods, or women suffering from any form of ovarian or uterine derangement; it usually disappears after the menopause. Chloasma may also follow dyspepsia, and is popularly associated with hepatic disturbance (C. hepaticum, liver spot). This form of the disease may be mistaken for tinea versicolor. It is noteworthy that the local pigmentation resulting from the application of mustard, cantharides, iodine, or chrysarobin may sometimes be permanent.

Diffuse Pigmentation of the Skin.

—The skin often becomes of a deep bronze tint from prolonged exposure to the sun's rays or to vicissitudes of climate ("morbus erroneus"). A similar condition may accompany Addison's disease, Graves's disease, chronic tuberculosis, carcinoma and malaria, or may result from the prolonged administration of arsenic or of nitrate of silver ("argyria"); in the latter case the colour is greyish-blue, and is due to the deposit of the reduced metal in the skin. Pigmentation of the skin may complicate varicose eczema, senile atrophy of the skin, scleroderma, leucoderma, lepra, psoriasis, and any chronic eruption accompanied by severe itching and scratching, especially pediculosis and prurigo. Deep pigmentation follows the subsidence of some forms of papular syphilis and erythema, also of purpura and lichen planus. Occasionally, malingerers and hysterical persons paint the skin to simulate disease. The pigment is always easily removed with a dilute solution of chlorinated lime.

Treatment must first be directed towards remedying any accompanying constitutional disturbances. Pigment is best removed by the continuous application on lint of a sufficiently strong alcoholic solution of corrosive sublimate to remove the epidermis and with it the pigment (usually about 1 per cent.), dressing the part afterwards with starch powder. The new epidermis is at first devoid of pigment, but it usually returns subsequently. The same purpose may be more slowly but less satisfactorily accomplished by dilute solutions of acetic or hydrochloric acid used as lotions. Quite recently Unna's salicylic acid plasters, applied for twenty-four hours consecutively, have been much used.

J. J. PRINGLE.

CHLORAL HYDRATE, Poisoning by.—The *symptoms* of an over-dose of hydrate of chloral are profound sleep, stertorous breathing, and flushed face; at first, the person can be roused, but the coma gradually increases, the body temperature sinks, and death follows with more or less of collapse. Dangerous and fatal symptoms are more readily produced in drunkards than in healthy subjects. The drug is frequently used in combination with bromide of potassium, which aids it in producing dangerous symptoms.

The *post-mortem appearances* present nothing at all characteristic; there will be the usual signs of death from asphyxia,

and the brain may show an excess of cerebro-spinal fluid.

Treatment.—The chief object is to combat the loss of body heat; placing the patient in a warm atmosphere and surrounding him with hot bottles, the inhalation of warm air, and stimulation of the skin by friction are the best methods to attain this object. Artificial respiration and the application of both the constant and induced currents to the chest and limbs may be tried to overcome the coma. The stomach pump should be used or emetics given, and the hypodermic injection of strychnine (gr. $\frac{1}{5}$) has been recommended.

Chronic Poisoning.—Amongst the ill effects of the habitual use or abuse of this drug, those relating to the nervous system are the most notable. Mental enfeeblement, melancholia, and mania have sometimes been traced to abuse of chloral. An erythematous or scarlatinial rash is apt to appear, and is often followed by desquamation and albuminuria. There may be acute general eczema. The use of the drug should be at once and entirely abandoned.

CHLOROSIS is the most common form of idiopathic anæmia; it received this name from the peculiar greenish tint of the complexion which characterizes it. The affection is practically limited to the female sex, and is most common about the period of puberty and early womanhood. It is often, but not invariably, associated with amenorrhœa, rarely with menorrhagia; and, although styled "idiopathic," its occurrence is favoured by many conditions, which possibly may operate in conjunction with the essential cause which as yet remains unknown. It must be remembered that it occurs at a period of life when the organism is undergoing an important evolution, when the menstrual function is about to make an increased demand upon it, and when, therefore, it may reasonably be supposed to be more amenable to influences tending to produce anæmia. At any rate, chlorosis is common in girls who follow sedentary occupations, or are exposed to fatigue, or live secluded from sunlight. In order, however, to account for its supervention, an explanation has been sought in an arrest of development of the vascular system, which is believed to become inadequate to the performance of the increased function demanded from it. Others, again, have referred chlorosis to a deficiency in the gastric secretions, or to a "self-intoxication"

from the absorption of fermentation products resulting from gastric dilatation or fæcal retention—the latter view being supported by the good results attending the administration of aloetic purgatives. So far as an examination of the blood goes, the chlorotic condition would seem to be more allied to imperfect formation of corpuscles than to their excessive disintegration, a derangement of hæmatogenesis rather than of hæmatolysis. But the subject remains one of the most obscure in pathology.

The *blood* in chlorosis is (1) paler than normal, owing to a marked deficiency in hæmogoblin rather than of red corpuscles, for, although the latter are below the normal in number, the percentage amount of hæmogoblin is almost invariably less than that of the corpuscular richness. (2) It is also more watery than normal, and the corpuscles do not tend to form rouleaux so readily as they do in healthy blood. (3) It is said to be deficient in serum-albuminates, but more observations are needed on this point. (4) As to the corpuscles themselves, there is no manifest disproportion between the numbers of the white and red globules, but the latter occur in greater variety as to size than in health, many being smaller (microcytes) and some larger (megalocytes) than the average.

The *symptoms* of chlorosis are well marked. They are those common to pronounced anæmia, of which, indeed, this form is often taken as the type. First, there is the colour of the skin and visible mucous membranes. The former is often of a waxy pallor, with, perhaps, a slightly greenish or yellowish-green tint, easily distinguished from jaundice by the pearly whiteness of the sclerotics. The cheeks have often a pinkish flush which contrasts markedly with the surrounding pallor. The lips are notably pale and bloodless, and the conjunctiva, observed by everting or drawing down the lower lid, is also markedly pale. The bed of the nails shows well the pale and bloodless character. The general nutrition is apparently unaffected, or, at any rate, there is no loss of subcutaneous fat, often indeed the reverse—viz., a tendency to an excessive deposit of this tissue. But in contrast to this apparently good nutrition there is marked debility, or rather muscular feebleness, the subject being readily fatigued. As regards the nervous system, the chlorotic is generally rather slow in intellect and prone to sleep. She presents often in a well-marked

degree the condition described as "neurasthenia." Effort, both mental and physical, is a weariness to her, and, although her sleep is heavy, it is unrefreshing, and frequently in the morning hours she will be torpid and somnolent, becoming bright and wakeful towards evening. Sometimes, however, the condition is rather the reverse of this, and she is irritable and restless, suffering much from headaches, which are not specially localized, being mostly either frontal or occipital. Hysterical phenomena are not very common, although the older writers laid stress on the caprice and waywardness of the appetite. One of the most frequent symptoms complained of is breathlessness, especially on exertion. She finds it increasingly difficult to mount stairs, or do any work requiring effort, without panting for breath. Yet the lungs exhibit no physical signs of embarrassed circulation. The characteristic signs are those of the circulatory system. Subjectively the patient may complain of palpitation. The heart's action may be rapid, and is always easily excited. On examination there is generally to be found evidence of enlargement (? dilatation) of the left ventricle, shown by a slight outward displacement of the apex beat, and an increase in the lateral dullness. Sometimes also a faint pulsation is visible in the third left interspace near the sternum (? auricular). There is invariably a systolic bruit, loudest over the pulmonary area, but often audible over the whole præcordia. The character of this bruit is mostly soft and blowing, but is sometimes so remarkably harsh and grating as to be mistaken for pericardial friction (it has, indeed, been suggested that it may be due to an unusual dryness of the serous membrane). Nor is there agreement as to its precise mode of production, the two main views being (1) that it is generated in the pulmonary artery, by the altered quality and perhaps also the diminished quantity of the blood; and (2) that it is a true mitral reflux, from the closure of the valve being rendered imperfect by the weakening of its muscles and the dilatation of the ventricle, the unusual site of a bruit so generated being explained by the retraction of the lung uncovering the auricular appendix. On either view the lessening and final disappearance of the murmur with the restoration to health is explicable. Besides this bruit, systolic murmurs are often heard over the aortic and tricuspid

area and in the larger arteries on the slightest pressure, perhaps because of the more yielding nature of the vessel walls. Almost as invariable is the jugular hum, or "bruit-de-diable," or "humming-top bruit," which can be heard over the jugular vein at its termination, often better over the right than the left vein. This murmur, when at all well marked, is invariably accompanied by a thrill. The bruit-de-diable is readily recognized by its continuous character, although its pitch rises with inspiration and falls with expiration. It is also louder when the patient is in the upright posture than when lying down. A similar venous hum may be heard occasionally on auscultation over the lateral sinus or the torcular Herophili. The order of appearance of the hæmic murmurs is usually as follows:—(1) The venous hum or the bruit-de-diable; (2) The systolic murmur in the pulmonary area (second left interspace); (3) A systolic murmur at the apex, indicating the occurrence of mitral reflux; (4) A similar murmur in the tricuspid area; (5) A systolic murmur in the aortic area. The murmur of mitral reflux is only present in advanced cases of chlorosis, and is usually the last to disappear when recovery is in progress. In well-marked cases of chlorosis there is slight œdema about the ankles which disappears after a night's rest, and perhaps slight puffiness of the lower eyelid. Perhaps the swelling of the optic disc occasionally found is really of dropsical origin. Marked neuro-retinitis has been met with in severe cases, but is very rare, nor are retinal hæmorrhages frequent (see ANÆMIA, PERNICIOUS). The pulse is rather quick, and often of comparatively high tension, which does not accord with the oligæmic view. On the other hand, it may be soft and compressible. The digestion may be deranged. Gastralgia is common, and the appetite variable. The writer is unable to confirm the statements made as to excessive capriciousness in this respect; generally there is more or less pronounced anorexia and discomfort after taking food. Vomiting is not common. Gastric ulcer is an occasional, but by no means frequent, complication. Constipation is the rule. The urine is copious, pale, and of low specific gravity, but is variable in this latter respect, some observers finding that there is excessive excretion of urea and uric acid, although pigmentary matters are deficient. Amenorrhœa is a frequent concomitant, and for the most part must be attributed to the anæmic

state. Lastly, there may be some pyrexia, especially in severe cases.

The *diagnosis* of chlorosis is easy, provided that a sufficiently elastic interpretation be placed upon the term. If sex and age concur, and if there be no evidence of any anæmiating disease (and the possibility of phthisis must be always borne in mind and carefully excluded), then the case may fairly be included under this head. But the difficulty arises in distinguishing this special form of anæmia and those forms which are more clearly traceable to conditions of life, from the grave form of idiopathic anæmia, which proceeds sooner or later to a fatal termination, particularly as cases which at their outset conform to all the characters of chlorosis may ultimately pass into progressive pernicious anæmia.

Treatment is hygienic, dietetic, and medicinal. The withdrawal of the patient from insanitary surroundings, and the exchange of a town life for a country life, are measures of a certain value, and show the influence which exclusion from sunshine and pure air has in the production of the disease. Exercise should at first be reduced to a minimum, rest in bed having an especially good effect, particularly upon the overworked milliner or domestic servant of town. Massage is useful, but seldom needed, recovery being often very rapid without recourse to it. The diet should be regulated, and, as soon as possible, meat should be given. An occasional aloetic purge may be necessary. For restoring the blood in cases of chlorosis there is no remedy equal to iron, which should be given in large doses. Blaud's pills, composed of the dried sulphate of iron (grs. ijss) and carbonate of potash (grs. ijss) with pulv. tragacanth (q.s.) (three, four, or five pills to be taken three times a day), are often all that is needed. Sir A. Clark, who attributes the anæmic state largely to the absorption of products of fæcal retention, thinks more value is to be attached to purgation than to tonics. It is, however, rarely necessary to administer a purgative with Blaud's pills. Iron in any form is useful, and, when the sulphate or perchloride are ill borne, the milder preparations, or ferruginous waters, as those of Schwalbach or Pyrmont, may be tried. Iron rarely fails to rapidly increase the hæmoglobin, but, when progress is slow, arsenic may be given, either in combination with, or in substitution for, iron. The mineral acids, especially hydrochloric,

are of considerable service when digestion is feeble. Cold baths, and sea bathing in moderation and with due precautions, are useful. Cases of chlorosis are specially liable to relapse if treatment be discontinued as soon as the colour returns to the cheeks; it is therefore essential that the treatment should be persevered with for a prolonged period and re-commenced on the first sign of a return of the condition.

SIDNEY COUPLAND.

CHOLERA is a generic term which has been somewhat loosely applied to a series of acute diseases, mainly characterized by copious intestinal flux; these are Asiatic Cholera, English Cholera (cholérine, cholera nostras), and Cholera Infantum.

CHOLERA ASIATICA is an acute specific disease, occurring in temperate climates as an epidemic only, and characterized by copious discharge of watery fluid from the alimentary canal, suppression of urine, and collapse.

The *symptoms* are divisible into three stages. The most prominent symptom of the *first stage* is the so-called "premonitory diarrhœa;" the stools are copious and watery, and the patient experiences great depression, epigastric sinking, and nausea. In severe attacks, and especially at the commencement of an epidemic, this stage may be absent, the patient becoming suddenly affected by symptoms characteristic of the *second stage*.

The stools are now very frequent, and the watery fluid passed ceases to be bile-stained, and becomes colourless or opalescent, with floating flocculi—the rice-water stools. Vomiting shortly becomes a prominent symptom, the contents of the stomach being first rejected, and then all the water which the patient, impelled by a violent thirst, is eager to drink; this is mixed with mucous and epithelial débris, so that the vomited matter much resembles the stools. Painful cramps in the muscles of the extremities and the abdomen ensue; the pulse becomes rapid (90 to 100) and progressively weaker, the respiration hurried, and the temperature in the mouth and axilla sub-normal; the patient, though prostrate, is restless, his voice husky, his face pinched, and the skin inelastic.

The second stage, which lasts from two to fifteen hours, gradually passes into the *third, algid, cold, or collapse stage*.

The purging and vomiting now either

cease or diminish, but the signs of prostration and imperfect aëration of the blood increase. The temperature in the mouth and axilla is 4° or 10° or even 20° F. below the normal, but the rectal (or vaginal) temperature generally ranges between 100° and 102° F., but may be as high as 108° F. in cases about to terminate fatally in this stage; the pulse is imperceptible at the wrist, and may also disappear from the brachial and carotid arteries; the first sound of the heart may be inaudible; respiration is very shallow and hurried. If a vein be opened, only a few drops of dark, viscid, "tarry" blood escape, and the imperfect circulation is evidenced by a leaden hue, especially marked in the extremities, face, and tongue. All the soft tissues of the body appear to shrink, the face becomes hollow, the eye-balls dry, sunken, and bloodshot, beneath half-closed lids. The skin is inelastic, often covered with clammy perspiration, and cold; the expired air also is cold. The excretion of urine and bile ceases, the voice is a whisper, and the patient, who is at once restless and apathetic, complains only of thirst, unless the cramps which are a prominent symptom of the second stage persist. Death may thus gradually be brought about after, on an average, twelve hours of the third stage. Occasionally the patient passes so rapidly into the collapse stage that diarrhoea does not occur, the whole duration of the illness being only a few hours.

If death do not take place in about twenty-four hours (more or less) *reaction* sets in. (1) This may be imperfect; if so, the patient becomes semi-comatose, the suppression of urine persists, the skin remains cold and clammy, but dusky-red instead of leaden. Though the pulse at the wrist becomes perceptible, respiration is still hurried, and death ensues in a few hours. (2) The reaction may be so little marked that the patient passes at once into convalescence by the mere cessation of symptoms and the reappearance of urine. This is of especial frequency in cases of cholera occurring in the Tropics. (3) Reaction may be well marked, and for ten or twelve days the symptoms may resemble those of enteric fever in the second week; the temperature is 2° or 3° above the normal, the pulse full and quick, the respirations are a little hurried, the face is flushed, the skin becomes red and hot, and may present an eruption (roseolar, or more rarely erythematous, urticarial, or vesicular). The stools, which are at first pale-yellow,

watery, and sometimes blood-stained, soon begin to contain bile, and have a pea-soup character, but are very fetid. The urine is scanty at first, and contains a very small proportion of the normal solids. In about half the cases it is albuminous, and it may contain casts. The tongue is dry and furred, and low muttering delirium is often present. Death during reaction may be preceded by cerebral symptoms (convulsions, coma), probably of uræmic origin; or it may be brought about by pulmonary engorgement and œdema, by gastro-enteritis, or by asthenia. Convalescence in more favourable cases may be delayed by subcutaneous abscesses, parotid suppuration, and sloughing of the cornea.

It is the duty of the physician in charge of a case of cholera to see that the stools and all soiled linen are thoroughly disinfected. This is best done with the solution of the perchloride of mercury (*see DISINFECTION*). Where cesspools are in use, the dejecta, after disinfection, should be buried in a deep pit, situated as far as possible from wells and streams.

The *diagnosis* of Asiatic cholera cannot be made by the presence of any pathognomonic symptom, as severe cases of simple cholera or choleraic diarrhoea may present all the symptoms of mild cases of Asiatic cholera. The history of the individual as to recent residence in an epidemic area, or the probability of the locality having become an epidemic area, are the most important elements in the diagnosis.

During the epidemic prevalence of cholera, cases of collapse from rupture of the stomach or intestine, and cases of internal strangulation and poisoning by arsenic have been mistaken for that disease. At such times it is prudent to treat every case of severe diarrhoea as a case of cholera, although the absence of the "cholera-voice" and the maintenance of a good pulse, together with the general aspect of the patient, may enable a physician with special experience of cholera epidemics to speak with confidence.

The early recognition of a commencing epidemic prevalence is a matter of the greatest importance; for this the individual practitioner must depend on a properly organized national and international health service, which will derive assistance from the bacteriological examination of stools from suspected cases. The discovery of the comma bacillus of Koch would afford weighty if not con-

clusive evidence of the real nature of the disease.

The rate of mortality varies from 10 or 20 to 66 per cent. of attacks in different epidemics, and is not less in temperate than in tropical climates; the average is stated at over 50 per cent. (Hirsch).

The *prognosis* is therefore always grave; the rate of mortality already obtaining during a given epidemic and the probability that the earliest cases observed in any locality will be the most severe must be taken into account. The early onset of the collapse stage is the most unfavourable sign; not more than one out of three patients in whom this stage is well established recover. During the second stage the condition of the pulse and heart is the best guide, early signs of cardiac failure, especially the disappearance of the radial pulse, being of very serious import. A high rectal temperature (104° F.) is also unfavourable. The more rapidly reaction is established the better is the prognosis. During the early period of the stage of reaction continued suppression of urine, high temperature, blood-stained stools, roseolar or other eruptions, and pulmonary complications are unfavourable signs. Cholera is more fatal in children, old people, and weakly persons than in robust adults. It is doubtful whether early treatment lessens the severity of an attack.

The *pathology* of cholera has been fiercely discussed by rival schools. It will be admitted that the disease has travelled into Europe on five occasions. In its first period of pandemic prevalence (1817-23) it passed from India through Persia, and first reached Astrachan in European Russia. In the second period (1826-37) it reached Russia by way both of Bokhara and of Persia; from Russia the disease spread to Germany and from Germany (Hamburg) to England (Sunderland) and thence to Ireland. Subsequently it was carried by Irish emigrants to Canada. In the third pandemic prevalence (1846-63) the disease again travelled by way both of Bokhara and Persia to Russia, from Russia to Germany, from Germany (Hamburg) to England (Hull), and again it was carried to the United States by emigrants. But in the fourth (1865-75) and fifth (1883-87) pandemic prevalence the disease reached Europe at the Mediterranean littoral by way of the Red Sea and Egypt; it also travelled on these occasions with very much greater rapidity. A more minute examination entirely confirms the impres-

sion thus gained that cholera follows lines of traffic. It is, however, not communicable directly from man to man, and can only become epidemic in places which present certain local conditions of atmosphere and soil. The disease ceases to spread or becomes extinct during a continuance of cold weather, and is favoured by a moist, but not saturated, state of the soil. It is most intimately related to water supply, but may be transmitted by milk (probably through added water) and possibly by other foods; persons residing in an epidemic area who do not drink water, or are careful to drink pure water only, generally escape, whilst those residing without the area who drink the water of the area may suffer. The purity of the water supply, the prompt isolation of imported cases, and disinfection of their discharges probably account for the recent immunity of Great Britain from this disease.

The *specific virus* is undoubtedly contained in the rice-water stools, probably in them alone; they are capable of rendering large bodies of water pathogenic, and their virulence increases for some hours or days after they have been passed. The conviction that the virus must be a living organism has led to the stools being very carefully searched, and numerous micro-organisms have been discovered. The only one to which any importance can be at present attached is the so-called "comma bacillus" of Koch. If it be granted that cholera is a specific disease due to the presence of an organized virus, it seems probable that the organism develops in the intestinal canal, as the "comma bacillus" is known to do. Some would attribute all the other symptoms to this draining away of fluid, the inspissation of the blood leading to retarded circulation, to arrest of urinary secretion, and so to excrementitious poisoning. Others, whose views have received confirmation by the discovery of ptomaines produced by the comma bacillus, believe that a chemical poison enters the blood, produces spasm of the arterioles, especially of the pulmonary arterioles, and so leads to local and general asphyxia. Upon this latter view the rice-water stools are a paralytic secretion due to inhibition of the abdominal sympathetic by the poison. Experimental section of all the nerves of the intestine produces a similar over-secretion of watery fluid.

The most distinctive *post-mortem appearances* observed when death takes place in the collapse stage are a shrunken, dry

state of the tissues, a swollen, injected condition of the gastro-intestinal mucous membrane, with detachment of the epithelium in flakes. Ecchymoses and a sticky state of the serous surfaces, distension of the right side of the heart and of the pulmonary artery, collapse of the lungs, which are also exsanguine, and an inspissated condition of the blood, are appearances commonly met with. Rigor mortis sets in early, and may cause curious post-mortem movements. The temperature usually rises after death. The detachment of the flakes of intestinal epithelium occurs post-mortem, but it is a matter of dispute whether the distension of the right side of the heart occurs before or after death.

Treatment.—The results of treatment are unsatisfactory. During periods of epidemic prevalence it is universally admitted that every case of diarrhoea should be treated as though it were the diarrhoea of the early stage of cholera, and many physicians with Indian experience believe that cholera may be thus aborted. The first indications are rest in bed and the withdrawal of all food and drink, the patient being only allowed to suck ice. Counter-irritation by a mustard poultice to the epigastrium, or a wet abdominal pack, made by placing a folded wet towel on the abdomen and swathing the body in dry towels, relieves the patient. In India the general practice is to give opium combined either with an astringent (*e.g.*, opium gr. j, plumbi acetatis gr. iv, dissolved in water, and repeated after each loose motion until three doses have been taken) or with a stimulant, or in combination with both a stimulant and an astringent. Calomel in a single dose of 2 to 5 or even 30 grains, followed by repeated doses of opium, has been recommended. Others, who regard the diarrhoea as eliminative, recommend evacuant treatment by castor oil in doses of half an ounce, frequently repeated. All are agreed that when collapse is threatened or has set in opium ought not to be given, and that during the second stage it does not check the colliquative diarrhoea—is, in fact, probably not absorbed, and that, if given during collapse, it may subsequently produce toxic symptoms if the stage of reaction be reached. Sulphuric acid lemonade (℥xv in ℥j) is grateful to the patient, if not useful. Cramp may be treated by hand-rubbing, by the hypodermic injection of small doses

of morphine cautiously given, or by inhalation of ether. In the collapse stage no drugs are of much avail; brandy, iced champagne, and diffusible stimulants are of doubtful advantage, but, if the diarrhoea have ceased, enemata of warm beef-tea and brandy may be given. A general bath at 98° to 104° F. relieves muscular cramp and the feeling of distress, and may be followed by sleep and recovery. The injection of warm saline fluid into a vein is followed by a remarkable improvement: the pulse improves, the patient regains his faculties, and is able to sit up; this amendment is usually of very short duration, but the treatment appears worthy of trial, and recoveries have taken place after a second injection. The fluids used have been—(1) Warm water containing phosphate of sodium and common salt, of each $\frac{1}{2}$ per cent.; (2) warm water (110° F.) containing common salt 60 grains, chloride of potassium 6 grains, phosphate of sodium 3 grains, carbonate of sodium 20 grains, and absolute alcohol 2 drachms, in 1 pint; (3) "artificial serum."

The treatment of the stage of reaction is chiefly that of the complications. Of these the most serious is a continuance of suppression of urine; for this the patient should drink freely (Oss every second hour); dry cups or a mustard plaster should be applied over the loins, and a mixture containing liq. ammon. acet. ℥ss, combined with tinct. digitalis ℥v-x, or even tinct. cantharidis ℥x, may be given every two or three hours, to six doses. Too much food should not be allowed during the stage of reaction. Iced milk, beef-tea, chicken-broth, and arrowroot may be administered in small quantities at short intervals. If vomiting be troublesome, beef-tea and brandy enemata may be given. In some cases, however, small quantities of solid food are retained by the stomach. Carbonate of sodium and chloride of sodium, given either with the food or in a mixture, will help to restore the salts of the blood.

Persons residing in a locality where cholera prevails ought to observe certain precautions: the water used for drinking should be boiled and filtered, or imported natural mineral waters should be drunk; all milk ought to be boiled; no food which has been in the room of a cholera patient should be used. Purgative and laxative remedies and fruit must be eschewed.

DAWSON WILLIAMS.

CHOLERA INFANTUM is an acute disorder attacking infants and young children, observed only in warm weather, and characterized by uncontrollable diarrhœa and collapse. It is closely allied to, if not identical with, cholera nostras, but is both more prevalent and more fatal. The onset of symptoms may be very sudden, the infant being seized with violent vomiting and purging, quickly followed by collapse. In other cases diarrhœa comes on gradually, often accompanied or preceded by drowsiness, then vomiting begins, and lastly collapse ensues.

When the disorder is fully established, the *symptoms* are—Vomiting, at first the contents of the stomach, then a watery fluid containing more or less bile; diarrhœa, the stools being at first feculent, thin, and offensive, but soon becoming watery, inoffensive, and almost like urine; prostration, sunken eyes, pinched features, flaccid abdomen, inelastic skin, and an extraordinary shrinking in size of the whole body. The tongue is at first clean, but later is coated with a thin fur, which eventually becomes dry and brown; thirst is constant, but even water is generally vomited; the pulse is rapid, and the internal temperature raised (to 104° or more), although the extremities are cold to the touch; the patient is restless, but drowsy. With pronounced symptoms such as these, the child generally passes into deep collapse, drowsiness increases, diarrhœa continues, vomiting ceases, the features become still more pinched and livid, the eyes half closed, and the temperature may rapidly fall below the normal. Death is generally preceded by coma. Convulsive phenomena, varying in intensity from clenching of the hands to well-marked general eclampsia, are almost always to be observed at some stage.

In favourable cases the rectal temperature falls, and the stools begin to be feculent; water is retained by the stomach; the diarrhœa gradually ceases, and finally nourishment can be taken.

The disease is, as a rule, of short duration; it may terminate fatally in less than a day; death usually occurs on the third day; convalescence is usually established, if at all, on the fifth day, or sooner.

The *diagnosis* depends upon the presence of uncontrollable vomiting and diarrhœa, intense thirst, rapid shrink-

ing of the whole body, copious serous stools, and early collapse.

The *prognosis* in a well-marked case is extremely grave; when collapse is established, death almost invariably ensues. Early cessation of vomiting, the appearance of feculent matter in the stools, or a fall in temperature are favourable symptoms.

The *morbid anatomy* is not very characteristic; there is evidence of catarrhal enteritis, with denudation of epithelium and enlargement of the solitary and agminated glands, follicular ulceration is frequent; nephritis (parenchymato-glomerular) is always to be found; catarrhal pneumonia is generally present, and there is cloudy swelling of the cells of the liver and other viscera. The stools, which are watery and almost invariably offensive, contain casein, and frequently also some serum albumen derived from the undigested milk.

The *ætiological conditions* appear to be the same for all forms of acute summer diarrhœa, whether observed in infants, children, or adults. The essential condition is a period of continued high temperature, during which the air temperature is never much below 60° F. A more exact parallel can be traced between the temperature of the earth at a depth of 4 feet and the epidemic prevalence of diarrhœa; this does not begin until the 4-foot earth thermometer touches 56° F., and the epidemic attains its maximum in the same week as the earth temperature reaches its highest point.

The conditions of town life, especially in the overcrowded dwellings of the poor, favour the disease, which attains its greatest virulence in closely built towns, where sanitation has been long neglected, and where a naturally loose and porous soil has become saturated with filth. Hand-fed infants suffer more than those at the breast, probably owing to decomposition or contamination of the milk.

The disease is probably in some way dependent on the activity of micro-organisms existing either in the soil or food, or in both, and there is reason to believe that it may be communicated by the emanations from the stools.

The *treatment* of this severe form of diarrhœa in infants is very unsatisfactory, the mortality of cases in which the symptoms are well developed being not less than 60 per cent. Milk should be withdrawn. If vomiting be marked,

only iced water should be given. Iced white wine whey, and chicken or veal broth, if retained by the stomach, constitute the best diet. Collapse must be combated by hot mustard baths (about 3j to the gallon), and brandy or ammonia in small and frequent doses. High fever and convulsions are indications for tepid baths (75° to 80° F.). Drugs by the mouth are generally rejected, and seldom produce much effect if retained. Among the drugs praised are mercury, in the form of the perchloride, gr. $\frac{1}{10}$, or grey powder gr. $\frac{1}{6}$ – $\frac{1}{2}$, or calomel gr. $\frac{1}{10}$ – $\frac{1}{2}$ (the latter combined with Dover's powder, gr. $\frac{1}{12}$). These should be frequently repeated at first. Nitrate of silver gr. $\frac{1}{12}$ – $\frac{1}{4}$; salicylate of lime (grs. iij–v every two hours at first) or salicylate of soda; naphthaline grs. iij–iv, resorcin gr. j, and other antiseptics may be tried. Hypodermic injection of morphine (by preference the sulphate), beginning with gr. $\frac{3}{16}$ in the earliest stage; bromide of potassium; enemata of ice-water, or of thin starch containing laudanum ℥ij and sulphate of copper gr. $\frac{1}{4}$; irrigation of the intestines with warm water containing nitrate of silver gr. j to 3j, and even irrigation of the stomach. When colic is severe in the early stage, one or two large doses of bismuth (grs. x), with Dover's powder, or in mixture with laudanum, are sometimes successful. After the stools have again become feculent, chalk and catechu will usually check persisting diarrhoea.

DAWSON WILLIAMS.

CHOLERA NOSTRAS (English Cholera) is an acute disease characterized by a copious watery intestinal flux and by collapse. It resembles Asiatic cholera in its general symptoms, but is of a much less severe type, has a very low mortality, does not spread as an epidemic, though it is often endemic, and frequently occurs sporadically. The disease is not well defined, and it is more than probable that the combination of symptoms to which the term is applied may be produced by more than one cause.

Symptoms.—In a typical case the patient is suddenly seized with nausea, perhaps ending in the rejection of the contents of the stomach, and speedily followed by purging, the stools at first being bile-stained. After a time the stools become less coloured, and finally consist of a watery fluid containing a little albumen. From the first there is a feeling of depression, with epigastric

sinking, which deepens into more or less severe collapse, in which the face is dusky and shrunken, the eyes sunk, the voice feeble, the pulse small and frequent, and the respiration hurried. The temperature quickly becomes subnormal. The severity of the symptoms varies very greatly, and a mild attack is not to be distinguished from one of ordinary diarrhoea, whilst a severe case may exactly resemble one of mild Asiatic cholera.

The *diagnosis* from Asiatic cholera rests mainly upon the absence of an epidemic of this disease, the general mildness of the symptoms, and the less marked collapse.

The *prognosis* is always favourable except in the case of old or enfeebled persons or very young children (see CHOLERA INFANTUM).

Etiology and Morbid Anatomy.—In fatal cases acute gastro-enteric catarrh has been observed. The symptoms appear to be due to the absorption from the intestinal tract of some poisonous material either ingested as such or produced there by micro-organisms. Finkler and Prior have described an organism nearly resembling, but not identical with, Koch's "comma bacillus" of cholera; other microbes have also been found in relation with cholera nostras, but none of these organisms have been proved to possess pathogenic properties.

Treatment.—The most important point in treatment is to withdraw all solid food and milk, allowing only iced barley-water and iced veal or chicken broth, and best of all iced water. The patient must remain in bed in a well-ventilated room. A mustard poultice or hot stupe should be applied to the abdomen; if there be much vomiting, it is better not to give drugs, and to allow only iced water, or lumps of ice. If much pain be present, laudanum ℥xv, with either the compound tincture of camphor 3j, or bismuth nitrate grs. x, may be given. Large doses of calomel (as much as a scruple) have been recommended in the early stage, but castor oil will generally be found as efficient. Prolonged diarrhoea may be checked by astringents, such as chalk and catechu, sulphuric acid (℥xij), and acetate of lead (grs. iij). Old, feeble, and very young patients often need free stimulation with brandy or iced champagne.

DAWSON WILLIAMS.

CHOREA (St. Vitus's Dance) is an affection characterized by spasmodic movements of the voluntary muscles.

Symptoms.—The onset is usually gradual, being preceded for some little time by failure of the general health. The child (for the patient is generally a child) becomes pale, excitable, restless, and fidgety, is clumsy with its hands, drops things, shrugs the shoulders, jerks the elbows, or has twitching movements of the fingers or face, from which latter it is often thought to be making grimaces. The gait is awkward—a sauntering, dawdling walk; sometimes one foot is turned in.

Such are the prominent features of the disease in a mild form. Parents and teachers are very apt to mistake the nature of the condition, and, believing the clumsiness to be due to want of care, try to break the child of the supposed habits by punishment, which only has the effect of making the condition worse.

Gradually the patient becomes more clumsy, fidgety, and helpless, and the face acquires a vacant imbecile look, which is very characteristic. When asked to put out the tongue, no notice seems at first to be taken of the request, but after a pause the tongue is suddenly protruded and as rapidly withdrawn. The speech becomes indistinct, partly from impaired power of articulation and partly from an aphasic condition; all degrees of this state up to complete speechlessness may be met with.

The action of the heart is often irregular, and in a considerable number of cases a systolic murmur is present, sometimes at the base only, and then presumably hæmic, but more often at the apex. Should a systolic murmur at the apex or base vary much from day to day, it may be hæmic in origin; but if well marked and persistent throughout the attack, it is almost certainly due to organic change. Presystolic or double apex murmurs in chorea are invariably the result of endocarditis.

In many cases, particularly in the early stage, one side of the body is more affected than the other, but it is most unusual for the affection to be limited to one side throughout the attack. Unilateral chorea has unfortunately been called "hemichorea," a name also used for a totally different condition which has absolutely nothing in common with chorea, and no little confusion has been caused thereby.

There may be at first no movements, but an apparent paralysis of one side of the body, a condition subsequently replaced by chorea. The movements of

chorea are distinguished from those occurring in any other form of nerve disorder by their non-rhythmical and purposeless character; the same muscles or groups of muscles never twitch twice in succession. As a rule, the movements cease during sleep, but in the worst cases the movements are incessant, and sleeplessness becomes a marked feature of the case. Such patients emaciate rapidly, and sores form on various parts of the body, either from injuries or friction, the result of the constant movement.

Incontinence of urine or fæces is almost unknown.

Death may occur from exhaustion and sleeplessness, or may be ushered in by delirium. Another cause of death is pericarditis, which may carry off the patient during the height of the disease or when the movements have practically ceased.

The *prognosis* in children is generally favourable, as the disease, when uncomplicated and left to itself, lasts as a rule from eight to ten weeks. In young adults the prognosis is not so good, the danger being especially great in those cases which seem to get well very rapidly, as maniacal or other grave symptoms may appear with great suddenness.

Complications.—Amongst the complications rheumatism is the most important; it may occur with or without endocarditis, or endocarditis may develop without articular rheumatism. Another rheumatic manifestation sometimes met with in cases of chorea consists in the formation of subcutaneous nodules in the fibrous tissues, especially in connection with bony prominences. They are most common about the patellæ or olecranon processes, the spinous processes of the vertebræ, and along the occipital ridge or on the frontal bone, but may be met with elsewhere, and have been observed in the abdominal wall. The nodules, which are fibrous in structure, come out in successive crops, are not as a rule tender, and gradually disappear. Nodules are more common in cases complicated by endocarditis.

An eruption, consisting of round, slightly raised red spots, which fade in the centre, enlarge and gradually disappear (circinate erythema), is not infrequently met with, and is also of rheumatic origin.

Post-mortem Appearances.—Endocarditis is almost always found, in the shape of a fringe of fibrinous beads along the free edge of the mitral valve; sometimes

the aortic cusps are also affected, less commonly the aortic alone. Pericarditis is often found, for, as already remarked, it is one of the causes of a fatal termination of the disease. In many cases the nervous centres have appeared to be healthy, but plugging of minute vessels in various parts has sometimes been found. Dr. Dickinson has described an appearance of dilatation of the medium-sized arteries and veins throughout the brain and spinal cord, also exudations and small hæmorrhages into the neighbouring tissues. It must be remembered, however, that it is only in the most severe cases that these changes have been found, and that, as in the very great majority recovery is complete, it is more probable that these changes are the effects rather than the causes of the disease.

Ætiology.—As no constant changes have been found in the nerve centres, chorea must be regarded as a functional disorder—a view supported by the fact, just stated, that recovery, when it occurs, is always complete, no permanent paralysis ever being left behind. It has been said that the affection sometimes becomes chronic, but such cases, when carefully examined, generally prove to be instances of repeated relapses, in which the intervals of freedom from movements have been overlooked. The frequent co-existence of endocarditis long ago led to the hypothesis that embolism of the arteries of the corpora striata was the cause of all the symptoms; but the extreme rarity of unilateral chorea, the fact that permanent blocking of large vessels is never met with, and the absence of embolism of other organs, are strong reasons for its rejection.

It has been suggested that in chorea there is a suspension of the acquired combined movements and a return to the purposeless, uncontrolled movements of infancy (at a period when the cortical centres are not fully developed)—*i.e.*, a functional disturbance of the cortex of the brain. The psychical and speech disturbances would fit in well with this view, but it is probable that other parts of the central nervous system besides the motor area are more or less affected.

Chorea is most common between the ages of five and fifteen, but is occasionally met with at an earlier age. It also occurs in young adults between eighteen and twenty-five. In children it is about three times as common in girls as in boys, and in adults, too, it is much commoner in women; in no inconsider-

able number of the latter it accompanies pregnancy. There is almost always some hereditary nervous predisposition in the family.

Many of the subjects of chorea have previously suffered from rheumatism; sometimes the chorea immediately follows an attack of rheumatism, especially when this is a sequela of scarlet fever. At other times only a family history of rheumatism can be obtained; other children have had it, or one of the parents. Endocarditis in the patient or in a member of his family may fairly be regarded as of rheumatic origin. But sometimes no evidence of rheumatism in the patient or his family can be obtained; even then it must not be assumed that the case is essentially non-rheumatic, for in children the articular manifestations of rheumatism are very slight, whilst the heart is quickly affected; and if the patient be kept under observation for several years it is almost certain that in a subsequent attack, or at some other time, evidence of rheumatism will be forthcoming. Inherited nervous excitability and rheumatic proclivity are both necessary for the development of chorea.

There are two exciting causes, apart from rheumatism, which demand attention. Fright or sudden emotion in a child predisposed to chorea is undoubtedly capable of inducing an attack. To be attributable to the fright, however, the chorea must have come on within a few hours after the mental shock. The other great exciting cause is over-pressure in schools. It is not only the dull children, who are being constantly worried by their teachers, who become the subjects of chorea, but quite as often, if not more so, the bright excitable precocious children, who are already learned out of proportion to their years, and who are ambitious of more knowledge.

It is probable also that insanitary surroundings and insufficient food have something to do with the causation, for chorea is far more common amongst the children of the poorer classes than those of the well-to-do.

It has been said that it may be due to imitation. Accounts of an epidemic of chorea in a school may be safely set down as instances of hysteria, but great authorities have declared that a child could become choreic merely from imitating another child with chorea. Such an occurrence is certainly extremely rare, and before this mode of origin is accepted in any given case it should be

shown that the child was not predisposed to chorea, and was not frightened by the movements of the affected child. Another point that might be urged against the imitation theory is the extreme rarity of the simultaneous occurrence of the disease in several members of a family. The possibility of chorea being acquired by imitation may be ignored in admitting a choreic child into a ward with other children.

Treatment.—Rest is the most essential feature of the treatment; the child should not be allowed to go to school, and great care should be taken to avoid excitement. In the mildest cases no further measures will be needed, but, if the gait be at all seriously affected, the patient must be kept in bed or on a sofa, and on no account be allowed to do any head work. The diet is always a matter of moment. As a rule, in the mildest cases meat may be allowed, but it must be pounded, as, owing to the involvement of the muscles of mastication, children are very apt to "bolt" their food. In more severe cases, milk, beef-tea, jelly, and milk puddings should constitute the main articles of diet. Stimulants are seldom called for, except in the most severe cases where there is great exhaustion and sleeplessness. If the movements be very violent, precautions must be taken to prevent the patient from being jerked out of bed, or wounding himself against the sides of his bed, and a chorea bed has been devised, consisting of a sort of box with deep, well-padded sides, in the bottom of which the patient's bed is made. In children, a better plan is to make a sort of hammock by fastening the sheets to the side of the cot, so that the child is suspended between them; there is then no risk of his doing himself any harm; but it is very seldom that the disease is so severe in a child as to call for this mode of treatment.

Of drugs, arsenic enjoys the greatest repute; the liquor arsenicalis may be given in 3-minim doses, to a child of six, three times a day, and the dose may be gradually increased till symptoms of poisoning appear, when it should be reduced, or the use of the drug suspended for a time. A child of ten years old will often be able to take 12 or 15 minims as a dose without ill effects. Conjunctivitis and vomiting are the principal warnings that the drug has been pushed too far. In some cases, after the continued use of arsenic in this way, patches of a more or less brown colour have been observed,

chiefly upon the neck. As soon as the disease is somewhat under control, it is advisable to reduce the quantity of arsenic. Iron is also useful, especially in the form of the syrup of the bromide; 10 minims three times a day being the dose for a child ten years of age.

Sulphate of zinc in increasing doses has also been much recommended; a grain may be given three times a day, and 1 grain added daily until a maximum of 25 grains is attained, when the dose should be diminished in like manner as it was increased. It is worthy of note that, when thus administered, sulphate of zinc does not produce any ill effects, as children taking the maximum dose have a good colour and look healthy.

In very severe cases morphine by the mouth or hypodermically may be required to ensure sleep, but, as a rule, chloral answers better. In adults a full dose of 20 grains may be followed, if necessary, by half the quantity in two hours, 5-grain doses being subsequently given every two hours until some impression is made upon the disease. Some very severe attacks have been completely cut short in two or three days in this way, but in other cases the plan has failed; in such, possibly, hyoscine might be of benefit. The administration of chloroform may be necessary, and without its aid it is sometimes difficult to feed the patient either with the stomach-pump or through a nasal tube. Cold douches and ice to the spine have been recommended, but their use is not as a rule attended with much benefit. In the chronic forms massage is often most useful. In severe cases the limbs may be protected by being wrapped in cotton-wool. Any rheumatic manifestation or complication would be treated on general principles.

JOHN ABERCROMBIE.

CHYLURIA is the name applied to a condition of the urine in which it presents the appearance of milk. It is believed to be due to the admixture of chyle and urine.

Characters.—The quantity of urine passed in twenty-four hours may be either normal or excessive—generally the latter. In colour it is white, milky, and faintly translucent, being much clearer after a period of fasting. When quite fresh it has a distinctly milky odour, and in most cases sets as a fragile jelly. After an interval, varying, according to different observers, from half an hour to

a few hours, the jelly liquefies, and the urine then consists of a creamy layer on the surface, a pinkish deposit, and an intervening thin whitish fluid. The deposit is sometimes very considerable, and of a distinct blood colour, so marked that a reddish tinge may be imparted to the whole fluid. The specific gravity, as in normal urine, generally varies inversely with the quantity, but it, like the reaction, has no special characters. The urine decomposes rapidly, and acquires a peculiarly fœtid odour.

Minute fat granules form the larger part of the microscopical appearances. With these are often found fibrin filaments and oval granular bodies (about four times the size of a red blood disc), which are probably immature ova of the *filaria sanguinis hominis*. Torulae, leucocytes, red blood discs, epithelium, urates, oxalates, and triple phosphates may also be found, but never renal casts. Larval *filariæ* are either present in considerable numbers or entirely absent. The chemical analyses of different specimens vary within such wide limits that the averages obtained from them have but little value. This is especially true of the fatty matter, which varies from 0.47 to 1.3 per cent. The other constituents show a more constant proportion—viz., albumin, about 1.4 per cent.; salts, 1 per cent.; extractives, including urea, 2 per cent. A trace of glucose is sometimes present. It will be noticed that the relative proportions of the different constituents are under no circumstances similar to those of normal chyle or lymph. The chylous character of the urine may altogether disappear for irregular periods.

Significance.—The majority of cases of chyluria are due to the presence of the *filaria sanguinis hominis*, and occur in those who have resided in tropical countries. The immature ova of this parasite are carried to and block the lymph streams in the glands or elsewhere. Anastomosing channels become distended, and a varicose condition of the lymph vessels has been found to obtain in many cases. From these vessels the contents may escape. When the lymphatics of the ureters and bladder are affected, and are thus filled with chyle, chyluria results. The post-mortem appearances in the bladder have often been described as normal; but the same may be affirmed of the stomachs of those who have died from hæmatemesis due to portal obstruction. The

absence of renal casts in the urine and of morbid appearances in the kidneys is said to disprove the occurrence of organic changes in these organs, but dilated channels in the neighbourhood of the renal tubules have been observed. Other evidence of the presence of the *filaria*, and also such symptoms as pain (lumbar, abdominal, or testicular) and dysuria, may be present. The red deposit so often found in chylous urine was formerly supposed to be due to hæmorrhage, but Manson has suggested that when the lymph becomes stationary in the vessels its development is continued beyond the stage ordinarily reached in the lymphatics; hence the occurrence of red cells and the red colour. The causes of the disease in Europeans who have never resided in the Tropics have not been determined. It may be due to the presence of other parasites, or to some unknown morbid condition producing a similar mechanical blocking of the lymphatics.

Treatment.—(1) *Prophylactic.*—The state of the drinking water must be carefully examined and its purity ensured.

(2) *Therapeutic.*—Gallic acid (5j–5ij per diem) internally and perchloride of iron as a vesical injection have been used, but not with much benefit. A tourniquet applied to the abdomen over the lumbo-sacral prominence is supposed, in a case of Dr. Dickinson's, to have produced its beneficial results by damaging the parent worm. (*Vide FILARIA SANGUINIS HOMINIS.*)

H. MONTAGUE MURRAY.

CINCHONISM is the name given to a group of nervous systems produced by the too long continued use of quinine or by an overdose of that drug. The first warning is usually a humming or buzzing noise in the ears, accompanied by more or less deafness; sometimes the deafness is almost complete, and persists after all other symptoms have passed off. Frontal or temporal headache is generally present, and may be very severe; giddiness is also a common symptom. Dimness of sight, though less constant than the affection of hearing, is tolerably common, and may amount to complete blindness; it is associated with pallor of the optic discs, narrowing of the branches of the retinal artery, and contraction of the fields of vision. There is also a tendency for the heart's action to be weakened, a fact that should be borne in mind in the treatment of such a case, and the patient warned against any sud-

den effort which might induce syncope. After very large doses collapse has been noticed.

An erythematous rash, limited to the lower extremities, has occasionally been noted as occurring after small doses of quinine.

To abandon the quinine is generally sufficient to effect a cure; carbonate of ammonia in 5-grain doses and stimulants may be administered internally if there be any tendency to collapse. The headache will be best treated by the use of cold applications locally and by the administration of saline purgatives.

CLAVUS.—An acute pain limited to a single spot in the head, and so called because the sufferer feels as if a nail were being driven in at the point affected. Clavus is generally associated with hysteria.

CLIMATE AND HEALTH RESORTS.—**Climate.**—In studying the climate of any country or district the following are the most important considerations:—The general geographical position of the locality, whether continental or insular, and its relation to larger or smaller seas or oceans; the peculiarities of its atmospheric conditions, and the composition and nature of its soil.

A rough subdivision may be made by classing the climates of all the regions between the Equator and the 35th parallel of latitude as "hot," all between the 35th and 55th as "temperate," and all between the 55th and the poles as "cold" climates. No sharply defined boundary line can be recognized between these subdivisions, and in some parts the characters of each, especially as regards temperature, may be extended much farther north or south than these lines would indicate.

It is a characteristic of all large continents that the climate is less equable than that of islands, owing to the varying relations to the influence of the neighbouring seas, the greatest inequality being observed at the greatest distance from the coast. The atmospheric conditions in like manner are greatly influenced by the proximity of seas and of mountain ranges, as regards relative moisture, purity of the air, and the prevalence of winds.

The nature of the surface soil, and more especially of the sub-soil, has a marked influence upon local climate in respect of the purity and the relative

dryness or moisture of the atmosphere.

The climate of the ocean is the most equable, and, if the sanitary arrangements of the vessel be complete, the purest of all. The ocean atmosphere is greatly charged with moisture and with certain gaseous materials, such as ozone, iodine, and bromine, which have a marked tonic effect upon the human organism, and in addition is free from the myriads of organic particles with which the air of continents or islands is loaded. When at sea in the latitude of the "hot" climates the sudden cooling of the air at sunset leads to a rapid deposit of atmospheric moisture upon all parts of the ship and its occupants, but the sensations of cold thus produced are far less than those due to a similar cause on shore, and hence are less to be dreaded by the invalid.

The effect of the ocean climate upon the human body in health or disease varies considerably according to the latitude and the peculiar features of each voyage. A voyage in a well-appointed sailing ship involves a very gradual transition from one kind of climate to another, and conduces to a dull and indolent habit of life, especially on the long voyages to Australia or New Zealand. In the fast steamships of the present day the transition takes place with surprising suddenness, and as a consequence the life of the traveller is more restless and active, the mind being either preparing for arrival at a new port or occupied with the departure from the old one. Under either set of conditions, however, a sea life involves a constant exposure to fresh, pure air and a complete freedom from many of the worries and cares of life on shore. It offers, indeed, the most perfect form of mental and bodily rest obtainable, provided that sea-sickness does not interfere with its enjoyment.

The principal voyages to be commended for purposes of restoring health are—(1) the Australian voyage round the Cape. This lasts, in a sailing ship, from seventy to ninety days, or sometimes longer, according to the weather experienced, and should be undertaken in the autumn, leaving England at the end of September or beginning of October.

Preparations must be made for cold as well as for hot weather, although the latter prevails over the greater part of the voyage. On nearing Australia, and especially after landing, the colder air and more marked contrasts of cold and heat must be guarded against. Risks of

catching cold, which on ship-board may be run with impunity, cannot be so lightly regarded on shore after a long voyage, and hence precaution both as regards clothing and ordinary habits must be observed. The same remark applies with equal force to diet, and the somewhat natural tendency to compensate for a long series of shortcomings on board ship by an injudicious surfeit as soon as the traveller gets on shore is very likely to be followed by the penalty of over-strained and disordered digestion.

Exercise is a very necessary feature of life on board ship, and its neglect is sure to lead to digestive disturbances, especially if, as is very often the case, the naturally increased appetite be allowed full satisfaction at each meal. It is desirable that the diet at sea should be plain in quality and moderate in quantity, and especially so when passing through the hot regions.

(2) The voyage to the Cape can only be undertaken with comfort in a steamship or a yacht. Leaving England at the end of September, the voyage will be fairly calm throughout, although there are possibilities of rough weather during the first few days out, and the last few when nearing the colony. The mail steamers call regularly at Madeira, and sometimes at St. Helena, and the voyage as a rule lasts about twenty-one days. The prevailing winds are south and south-east.

(3) The voyage to India presents fewer attractions from a health point of view owing to the extreme heat which may be experienced during part of the voyage; but it is the most generally interesting of all the long voyages. Much depends, however, upon the time of year at which it is undertaken. By leaving England early in October, a very pleasant journey may be expected, subject to the risks of rough weather in the Bay of Biscay, and sometimes in the Mediterranean, but the rest of the voyage will almost certainly be passed on an even keel. The return voyage should be made in March or April, and it is always advisable to delay the return to England till the end of May, as the cold winds of the English spring are especially trying to persons arriving from tropical regions. A few weeks may be spent in Egypt, Malta, or Southern Italy.

(4) The voyage to South America, if undertaken in the autumn, is fairly suitable for invalids. It must be borne in mind that the hot season in Rio de

Janeiro, Monte Video, and Buenos Ayres is our winter. The time occupied in getting to the latter port is about twenty-seven days from Southampton, and the service of steamships is excellent. The ports of call in South America—Pernambuco, Bahia, and Rio—are full of interest, and from the latter port excursions can be made into the interior, where the scenery is in many parts very beautiful. Sufficiently good accommodation is obtainable for any but the most pronounced invalids. The coast is hot, and a good deal subject to epidemics of yellow fever, but a few miles inland the temperature becomes cooler, the nights being very pleasant, and the dangers of fever to the ordinary traveller reduced to a minimum.

(5) The voyage to the West Indies, although full of interest to the traveller and sight-seer, is of less value from the point of view of health, as the time taken to reach St. Thomas from Southampton is rarely more than fourteen days, and the inter-insular voyages have to be made for the most part in small steamers, involving a good deal of change. The traveller should start in the winter months, as the summer heat is too great for Europeans in delicate health.

Island climates resemble those of the ocean in many respects, and particularly as regards their equability and the prevalence of steady winds. As health resorts their characters vary in different regions, and require special consideration. Of the islands nearest home, the Canaries and Madeira are easily accessible by steamers running between Liverpool and the West Coast of Africa. The Cape mail steamers also stop at Madeira every week, and at Grand Canary during the winter months.

The Canary Islands available for prolonged residence are the two central islands of the group, Teneriffe and Grand Canary. Santa Cruz is the chief town of the former, and Las Palmas of the latter, and both are now provided with good accommodation. Orotava, in Teneriffe, enjoys an almost perfect summer climate, and possesses a good hotel, open all the year round. A good hotel has also been established on the island of Palma. The climate of the islands is hotter, dryer, and less equable than that of Madeira, and is more subject to heavy tropical rains. The average number of rainy days, however, is very small, being at Orotava only about forty in the course of the year. The roads are good about Orotava and the Peak of Teneriffe, and

on the island of Palma the scenery is very beautiful. In other parts of the islands, however, it is rather tame. Outdoor amusements, of which there was formerly a great lack, are now rapidly increasing, but there is little or no shooting or fishing to be had. Mosquitoes are plentiful, and in some places in the Canaries the activity and voracity of the fleas present a real drawback to comfort, but with the introduction of more cleanly habits it is probable that this plague will be diminished. Communication between the several islands and with Madeira is now maintained by a good service of steamers. Spanish is the language of the Canaries.

Madeira, or rather its chief town, Funchal, has held its own as a sanatorium for many years. Its climate is equable, warm, and moderately moist, but the air is not bracing. The town of Funchal is built on a hillside, sloping down to the bay, and residence may thus be selected at any level above the sea. The town is protected from the prevalent winds, and is absolutely free from dust. The water-supply is good. There is much less of the chill at sundown than is usually experienced in such climates. The winter season begins in October; the rainy days are of the sub-tropical kind, heavy showers alternating with bright sunshine. The climate of other parts of the island is variable, and the weather often cold and stormy. The scenery of Madeira is very beautiful, but it can only be seen by travelling on foot or horseback or, as is the more common custom, in hammocks carried by relays of bearers, as there are no driving roads and no wheeled vehicles, and the paths near Funchal are rough and stony. Portuguese is the common language. The hotel accommodation in Funchal is exceedingly good, and there are always plenty of villas to be let for the season. Perhaps the greatest drawback to residence in Funchal is the large invalid population of various nationalities.

The dryer and more bracing air of Teneriffe is often more suitable to sufferers from pulmonary disorders, than the equable climate of Madeira, especially during the summer, and hence the seasons may be passed in either alternately.

The islands of Corsica and Sicily, like Madeira, derive their popularity as health resorts from the position of their chief towns. Ajaccio, at the head of a beautiful bay with a due south-west aspect, is well protected from the cold winds by the mountains to the north-

ward, and has a warm, moist winter climate, with no excessive range of daily temperature. The rainy days of the winter are usually about thirty-five. The scenery is fine, and the accommodation good. A new hotel has recently been opened. The town is fairly free from dust, and suits cases of chest disease when there is no tendency to active mischief, and is also excellent for certain cases of asthma. There is, however, but little accommodation for invalids, nor are there many English residents. Excellent shooting can generally be obtained in Corsica. Ajaccio is easily reached by regular steamers from Marseilles and Leghorn.

Palermo, one of the most beautifully situated of all the Mediterranean health resorts, possesses an equable winter climate, but is more moist and experiences more rainy days than most of the others. It is rather windy, but very free from dust. The Sirocco is sometimes felt during a part of the spring months, and the liability to changes of this kind and the excessive glare of the sun are the chief drawbacks to residence in the town. The climate appears to be beneficial to the more excitable types of phthisical invalids, but does not by any means suit those of bilious or phlegmatic habit. Hotel accommodation is exceptionally good at Palermo, and visitors may rely upon obtaining all ordinary comforts. The town is a good deal frequented by the English, both as visitors and residents. It is best reached by steamer from Naples.

Malta has nothing to recommend it as a health resort except the equability of its climate. As a naval station it has always a large proportion of visitors, and is hence attractive from a social point of view, but the island itself is dull and uninteresting, and the town of Valetta is by no means a pattern of hygienic arrangement.

Corfu, formerly one of the most favoured of winter residences, has now become less fashionable, owing perhaps to the inconstancy of its climate, which is moister, rather colder, and less equable than that of many other islands. It is very rainy during November and December. Hotel accommodation is good in the town of Corfu, although no special provision is made for invalids. Yachting is the principal amusement, and is remarkably cheap; good shooting is to be had in the neighbouring mountains of Albania. The spring climate is the best, but the island is liable to visits

from the Sirocco. High winds are often prevalent, and create much dust. Corfu is best reached by steamer from Brindisi.

The island of Capri, situated between the Bay of Naples and the Gulf of Salerno, presents one of the most perfect island climates, being very equable, fairly dry, and, although rather windy, well sheltered. The evening chill is much less felt than on the neighbouring mainland. The island is rather difficult to get at, and is approached either by open boat from Sorrento or else by one of the steamers from Naples, the voyage in either case being sometimes uncomfortable. The hotel accommodation is good, but there are no special arrangements made for the comfort of invalids, and hence none but those capable of getting about easily should select the island for residence.

The climate of the **sea-coast** stands next in importance from the therapeutic point of view. Two classes of coast climate may be recognized, having respectively a bracing or stimulant, and a soothing or sedative effect upon the human organism. In our own country the eastern shores are almost without exception of the former class, whilst the southern and western shores are more marked by the latter quality, although certain parts are more sedative and relaxing than others, owing to their peculiar natural features. The most striking characteristic of the climate of the British Isles, as a whole, is the constant liability to change, even within the space of a few hours. Except during a few weeks in the middle of summer and occasionally during the winter also, changes of barometric pressure and in the direction of winds may occur in the most irregular succession, rendering it wholly impossible to forecast the state of the weather for more than twenty-four hours in advance.

On the eastern coasts of Scotland, England, Wales, and Ireland the rainfall is about half that of the western coasts. Cold winds are, however, very prevalent during the early spring and late autumn.

The south coast, between Dover and Portsmouth, enjoys a rather higher mean temperature and as low a rainfall as any part of the east coast; but from Portsmouth to Start Point the rainfall is higher, and over Cornwall it is very much higher, than over the rest of the southern shores. The winds of the south and west are less keen, and there is a larger proportion of sun-

shine. The west of Scotland has a very moist climate during all but the hottest months of the year—a marked contrast to the dry and bracing atmosphere of the eastern counties. Wales, except upon the actual coast, has also a moist and variable climate. Ireland, like England and Scotland, is drier and more bracing on its eastern shores than on the west, the rainfall is rather less than that of either of the other British Isles, except in the province of Munster. The mean temperature ranges from 46° to 51° in all three countries, that of the western coast of Ireland, Wales, and Cornwall being higher than other parts of the kingdom.

Of the **sea-side Health Resorts** in this country almost all are frequented in the summer, the more bracing shores being the most popular. The following are the leading characteristics of those which are also available in the colder months, beginning with the Kentish towns nearest to London. The north coast of Kent, Herne Bay, Westgate, and Margate, are essentially bracing places, with strong sea-breezes. They are especially suitable to cases of scrofulous disease, and for convalescence after chronic illness or surgical operations. Ramsgate is milder and less exposed to wind, but is decidedly bracing in its effects. Dover, Folkestone, and Sandgate are cold in mid-winter, but pleasant in spring and autumn, and suit the early stages of phthisis and bronchial catarrh very fairly. Hastings has an equable, moderately dry climate, with abundant sunshine, and is comparatively free from fogs. It is most visited in winter, and is well suited for mild cases of phthisis and for convalescents. Eastbourne is more popular in summer, and is subject to much wind in spring. It is bracing, and has the advantage of being built a little inland as well as on the immediate coast. Cases of anæmia and ill-health after excessive town work do extremely well there, and phthisical patients find benefit during the summer months.

Brighton is especially tonic in its effects, and is most popular as a resort for recruiting after over-work or any debilitating illness. The Isle of Wight presents on its south coast the well-known Undercliff, on which the town of Ventnor is built. This is protected on its north, north-east and north-west sides by high cliffs, and is open

only to the sea on its southern aspect. The climate is fairly dry and very equable, and has a generally tonic effect, being especially suitable to cases of early phthisis, and to irritable conditions of the throat. Ventnor is visited in the early autumn and in the winter. It is hot during the summer months, but pleasant all the year round. Shanklin and Sandown, on the south-east side of the island, are moderately bracing, and especially suited for young children. Freshwater, on the south-western side, is more bracing than either, and gets a larger proportion of fresh sea breezes.

Bournemouth stands partly upon cliffs overlooking the sea and partly on the sides of a valley dividing the east from the west cliff. It has a great reputation as a winter resort, and is not too hot in summer, but its effects as a health resort depend in great measure upon the selection of the right spot for residence in each particular case. In some parts it is a good deal searched by cold winds, but in others it is protected by the large pine woods, which form one of the chief features of the place.

Sidmouth is quiet and sheltered, its climate closely resembling that of Ventnor.

Torquay presents several varieties of climate at the different elevations at which it is built, but it is for the most part damp and equable, with a large proportion of rainy days in the year. It is particularly suitable to elderly persons, to whom the soft and rather relaxing air is pleasant. Cases of chronic bronchitis and chronic phthisis with much catarrh are, as a rule, benefited. Irritable conditions of the pharynx also do well, so long as there is freedom from cold winds.

Penzance has a somewhat similar climate, but is subject to a still larger proportion of wet days.

Tenby, in South Wales, possesses a fairly warm winter climate.

Llandudno, in North Wales, is sometimes visited in the winter, but is subject to more cold wind and wet days than would seem to warrant the preference for it over the warmer and more equable places in the South of England.

France.—The average temperature is higher than that of the British Isles, the summer heat in the south averaging 80°. The winter temperature of the west and south coasts is much higher than that of any other part of the country,

and the climate is rather more equable. Central France is colder and very bleak in places. The south coast, especially about Marseilles is subject, during about half the year, to the north-west wind known as the Mistral—a clear cold current, generally most keen in the late afternoon, and often ceasing at night. It commonly produces clouds of dust, but is usually followed by a bright, unclouded sky. The average rainfall over the whole country is about 30 inches, except in the mountainous districts of the Pyrenees and Auvergne. Of the places on the coast of France available as health resorts, the principal are Biarritz, Arcachon, St. Jean de Luz on the west and Hyères, Grasse, Cannes, Mentone and Nice on the shore of the Mediterranean. Biarritz is popular as a winter residence for chronic invalids from November till March, but being subject to strong winds and a high degree of moisture it is not suitable to chronic lung disease. Its character as a health resort is defined as bracing and sedative. Arcachon also has the same effect upon the system. It is more protected from the prevalent winds, which, moreover, having to pass over a great inland arm of the sea, become more charged with watery vapour and marine exhalations. Like Bournemouth, Arcachon is particularly rich in pine woods. St. Jean de Luz has a climate allied to that of Biarritz, but is more protected from winds by the hills which surround it, and is hence suitable to some forms of chest disease.

The south coast of France enjoys a very large proportion of sunshine throughout the year. Coupled with this, however, are certain drawbacks. The whole of the coast is subject to searching winds during the spring months, especially to the Mistral already referred to, and the north-east wind or "Greco." A hot wind from the south-east is also felt and is a part of the Sirocco to which the South of Italy is exposed. The day temperature of most of the health resorts of the Western Riviera is not very high in the shade, but may rise excessively in the sun. At sundown there is a sudden and uniform fall of temperature, always trying, and sometimes disastrous, to invalids. This is generally followed by a slight rise after the lapse of an hour. The annual rainfall is considerable, but the number of rainy days is not great, nor is the air moist as a rule. The winter climate, of the Riviera must not therefore be looked upon as by

any means perfect, or as fulfilling all the requirements of invalids during the cold season, but it is as a whole a great deal better than most varieties of winter climate to be met with in the British Isles. Hyères lies about three miles from the actual shore in a spot protected from the north, south, and north-east, but exposed on its western side, and it feels the force of the Mistral excessively during March and February. The climate of the place as a whole is a little more equable than that of the actual coast itself, the extremes of heat and cold being less felt. Costabelle, close to Hyères, is more sheltered on all sides and is admirably suited for winter residence. Cannes is the favourite resort of the English colony on the Riviera. It faces to the southward, and extends inwards for a considerable distance from the shore, the ground as it gradually rises to the lower hills being dotted over with villas. The climate varies in different parts of the district, but is bracing and stimulating as a whole, and hence is suitable to anæmic persons or those with scrofulous affections, but does not benefit the nervous, irritable, or inflammatory types of disease. There is not much shelter from the winds, and a great deal of dust is encountered at times. Local advice is necessary in selecting a residence for convalescents.

Mentone is very well sheltered, especially in its east bay, which is still and warm. It is well suited for old people and for the more irritable forms of lung disease, but not for cases of hæmorrhagic phthisis. The place is generally quieter in respect to social gaieties than some of the other popular resorts, and has sometimes been described as "dull."

Nice retains great popularity as a winter residence, chiefly on account of its gaiety and social attractions. Its climate does not present any special advantages over some of the less known resorts. It is generally bracing, but not very equable. San Remo, although on the Italian side of the frontier, may be classed with the other health resorts of the Western Riviera. Its climate is equable and moderately bracing, and its situation sufficiently sheltered. It is well suited to the irritable and nervous types of cases.

Algiers possesses a pleasant winter climate, subject to a good deal of variation in different years. As a whole, the climate is hot and dry, but not excessively so. The rainfall is considerable, and the number of rainy days somewhat higher

than in other places at the same latitude. The rain comes in heavy showers, and the ground dries rapidly. Cold winds may be felt occasionally, but they are less easily borne here than elsewhere, owing to the contrast with the prevailing warmth. The Sirocco blows but rarely. The temperature is apt to fall suddenly at sundown, but the nights, as a rule, are mild and balmy. The town itself is divided into a French and a native quarter, the former being nearest to the sea. The sanitary arrangements are defective in both quarters, and the suburbs are best fitted for alien residence. Mustapha, situated on rising ground to the south-west, is the most popular. Villas are plentiful, but care is necessary in selecting a residence to see that the living rooms are well exposed to the sun, and that the sanitary arrangements are satisfactory. This suburb is said to be as well suited for summer as for winter residence.

Hammam R'lhra, an ancient bath known to the Romans, and situated about sixty miles from Algiers, offers attractions during the months of April and March, but the statistics of its average climate are not especially inviting. It is on high ground, 2000 feet above the sea. Hotel accommodation is good, and sport can be obtained. Close attention to the rules of hygiene, both as regards residence, habits, and food, are essential in Algiers.

Egypt has an exceedingly dry, but inequable, climate, except in the neighbourhood of the Delta, and hence Alexandria and the northern towns are not suitable as health resorts. Cairo is popular from its social comforts and advantages, but is not much to be commended to invalids. Although close to the Desert, it does not reap the advantage of desert air, and is much subject to dust. The sanitary arrangements are very defective. Helwan, in the vicinity of Cairo, and in the Desert proper, is now becoming more popular than the city, but the true Desert climate is best enjoyed by means of the Nile voyage. Eight hundred miles of the river are available before the Second Cataract is reached. There is good accommodation at Assouan and Luxor. From January to March is the best period of the year. The climate as a whole is intensely dry, and the nights are frequently cold, necessitating the precaution of warm clothing. The Desert air is as pure as that of the ocean, and is bracing and invigorating. There are no very great extremes of

temperature, but the fall at sundown has to be constantly borne in mind. The climate is very suitable for quiescent cases of phthisis and for old-standing cases of bronchitis, with much emphysema. Catarrhal conditions and dyspepsia reap considerable benefit, but the more irritable class of cases, with febrile or hæmorrhagic tendencies, are not much improved.

Mountain Climates have been much employed of late years for the treatment of the various stages of pulmonary phthisis. Their common characteristics are, rarefaction of the atmospheric air, with consequent diathermancy for the sun's rays, and purity and freedom from organic particles; clear skies, with abundant sunshine, and a fairly uniform low temperature in the shade. The effect upon the human organism is essentially bracing, the altered density of the air leads to increased respiratory movements and a more thorough interchange of gases. Appetite is increased, and all the functions of the body appear to be stimulated, always provided that the powers of the lungs, and more particularly of the heart, have not been reduced below a certain level by previous disease or overwork. The principal Swiss altitudes, Davos, Wiesen, Maloja, and St. Moritz are all excellently supplied with hotel accommodation of the best kind, and at most of them there is no lack of interest and amusement. Davos-Platz lies 5352 feet above the sea-level, and is available as a residence all the year round. It is especially visited in the late summer and winter and spring by persons in the early stages of phthisis, and hence contains a large preponderance of invalids among its inhabitants. The climate is fairly equable, but may vary considerably in different seasons. The relative amount of sunshine is high and the solar radiation is great, although the thermometer may be below the freezing point in the shade. The amount of wind is moderate, and is less in winter than in summer. Davos, however, is becoming subject to the common evils of overcrowding, and the food supply is capable of much improvement. St. Moritz, in the Upper Engadine, lies 5803 feet above the sea-level, and possesses a dry, warm climate during the summer months from June till September, when it is chiefly frequented. The nights are cool, and the prevalent valley winds are moderate. The village of St. Moritz stands higher, and at some little distance from the hydropathic establishments around which

the best hotels are congregated. These latter are not open during the winter months, but good accommodation is available in the village itself. Wiesen lies at a lower level than Davos, and is often used as a halting-place on the return journey. It stands at an elevation of 4770 feet, and its situation is dry, sheltered, and sunny, and although less frequented than Davos-Platz, it possesses most of its climatic advantages. The Maloja, in like manner, may be visited as a halting-place in the descent from St. Moritz, but it possesses special features which entitle it to rank in the first class of mountain health resorts. The accommodation recently provided has rendered it most suitable for winter residence. It is not overcrowded, and is subject to a good deal more wind than Davos-Platz. The latter is not by any means a drawback, and in some respects is a distinct hygienic gain, as preventing the possibility of stagnation of air or smoke. E. CLIFFORD BEALE.

CLITORIS, Diseases of the.—This organ may be **absent** or **malformed**, such conditions being usually associated with other malformations. **Hypertrophy** of the clitoris is met with, and is often associated with hypertrophy of the labia minora. It occurs as a racial peculiarity in Hottentots, forming the so-called "apron." It is less common in cold countries than in the tropical zones. Venereal excesses are supposed to favour its occurrence. Removal of the clitoris has been practised for the purpose of curing the habit of masturbation, but there is no trustworthy evidence that the operation has any effect upon the patient's condition or habits other than, considered as a mutilation, a harmful one. But should the clitoris be so large as to cause annoyance to the patient, its removal will be the only treatment. Hypertrophy differs from elephantiasis in that the clitoris remains of its natural shape, and the parts from which it springs are healthy.

Elephantiasis of the clitoris is often associated with similar disease of the labia. Together they may form a mass weighing as much as 20 lbs. It is an overgrowth of the sub-mucous connective tissue, associated with dilatation of the lymphatics and veins, thickening of the skin and mucous membranes, and an irregular warty polypoid overgrowth.

The *pathology* of elephantiasis will be considered elsewhere. It is rare except in

tropical countries. It occurs during the years of sexual activity. Instances of its transmission by inheritance have been described, but these perhaps should more properly have been called hypertrophy (see *FILARIA SANGUINIS HOMINIS*).

Ætiology.—Its causes (other than the presence of parasites) may be generalized as those of chronic inflammation, together with pruritus, injury, erysipelas, syphilis, gonorrhœa, excessive sexual excitement, and eczema. Pregnancy usually augments the growth. From the dependent position of the growth it is very liable to venous congestion, œdema, and ulceration.

Treatment.—Removal is the only cure.

Cancer occasionally affects the clitoris. It usually begins at the tip, and presents itself as a bright-red, hard, warty, ulcerated swelling, at first movable, having a narrow base of healthy tissue. In time the inguinal glands become affected. It should be treated by prompt excision.

Removal of the clitoris is best effected by cutting with the platinum knife of the Paquelin thermo-cautery, as the part is very vascular.

G. E. HERMAN.

CLONIC.—Spasms are called clonic when they intermit at short intervals, during which the muscles are in a state of relaxation. Clonic spasms succeed the tonic spasm of the first stage of an epileptic fit.

COAL GAS, Poisoning by.—This may occur in a variety of ways, but it commonly arises from an escape of gas into a room owing to faulty pipes or joints, or from carelessness in turning off. When the leak is underground and the gas permeates the soil before gaining access to the room, symptoms resembling those of typhoid fever are apt to be produced, headache and malaise being the most prominent. When the escape of gas takes place into a bedroom during the night, the occupant may pass into a state of insensibility without being aroused.

Dullness or stupor, passing on to coma, is the earliest symptom; the face becomes livid, the respirations shallow, the pulse feeble, the conjunctivæ suffused, and convulsions sometimes occur—a symptom of unfavourable omen. With regard to the pupils there is nothing characteristic. Vomiting is not uncommon, and the breath and vomited matters may smell of the gas.

If the person be not speedily removed from the impregnated atmosphere death is certain to follow, and even after removal it may happen unless active treatment be promptly adopted.

Treatment.—A free current of fresh air and artificial respiration should be first tried; brandy should be administered if the action of the heart be weak, and if there be much lividity the patient should be bled. Relapses are very common after improvement has commenced, and constant vigilance is therefore needed.

COCCYGODYNIA means pain in the coccyx. It occurs almost exclusively in women who have had children, and is usually dated from a confinement. The conclusion follows that it is, as a rule, due to injury during delivery; to overstretching or rupture of the ligaments uniting the coccyx to other bones, or to periostitis, dislocation or fracture of the coccyx. It is sometimes referred to accidental injury, or to excessive horse exercise.

Sometimes the presence of a fracture or dislocation, or of inflammation, can be ascertained by the signs indicating these conditions, but generally there is nothing to be perceived except that the patient points to the coccyx as the seat of pain, and pain is produced by pressure on, or movement of, this bone. The patient therefore often cannot sit comfortably, and defæcation is painful. Sometimes the coccygeal pain is merely part of a general pelvic pain, due to some morbid condition within the pelvis.

Treatment.—General tonic treatment (quinine, iron, and nux vomica) should be tried, in the first instance, together with rest and an aperient to ensure a daily soft evacuation of the bowels (mag. sulph. ʒj, vini aloes ʒj, in water every morning). In the majority of cases this will in time cure the patient. Should the pain be very severe, morphine may be injected subcutaneously over the coccyx. If there be a dislocation or fracture of the coccyx, causing it to be fixed in an abnormal position and so painfully press upon the integuments, the best plan will be to remove it altogether. In cases in which pain on moving the coccyx has been very persistent and other treatment has failed, good results have been reported from the subcutaneous division of the ligaments, muscles and fasciæ attached to the bone.

G. E. HERMAN.

COLD, Effects of.—The first effect of cold applied to the living body is to produce some congestion of the superficial blood-vessels; this is quickly followed by their rapid and extreme contraction. To this, in the healthy and robust, and provided the exposure to cold has been but moderate, the period of reaction succeeds, and is indicated by the ruddy appearance of the surface resulting from the re-dilatation of the capillaries and the augmented energy of the circulation. If the exposure to even a moderately low temperature be prolonged, and after but a short exposure to severe cold, especially in the case of the weakly and debilitated, no reactionary glow ensues, but a lengthened period of vital depression, which is accompanied by enfeebled nutrition, and followed by tedious recovery. The exposure may be so prolonged, or the cold so intense, as to induce not merely local and temporary vascular syncope, but local, or even absolute and general, physiological death; beyond this point the physical and chemical effects only of cold continue in force. Complete (physical) freezing of a tissue is never followed by recovery of the part.

The immediate and ultimate effects of cold are dependent upon—(1) The condition of the individual; the feeble, the aged, the young, the intoxicated, and those not previously enured to exposure succumb with comparative rapidity; (2) the method of its application—*e.g.*, water and moist air are good conductors of heat, and thus chill rapidly; heat is also quickly abstracted by the convection of strong winds, while exposure to *still* air at a remarkably low temperature can be borne with comparative impunity; (3) the area of the surface exposed; (4) the part of the body exposed—*e.g.*, outlying portions, such as the toes, fingers, the extremity of the nose, and the tips of the ears, where the circulation is most easily checked and less readily restored, not uncommonly suffer local death from “frost-bite” without any great disturbance of the general health, whereas prolonged application of but moderate cold to the head or the abdomen has been productive of fatal results.

The *local effects of cold* upon the tissues are illustrated by CHILBLAINS, FROST-BITE (*q.v.*), and gangrene (*see* DERMATITIS GANGRENOSA).

Dying from cold is attended with shivering, pallor, and lividity, puckering of the skin, increasing muscular stiffness and weakness, confusion of the senses,

profound unconsciousness; there may also be, for a while, intense thirst, obstinate insomnia, and almost every symptom, subjective and objective, of cerebral disturbance; and in such instances the symptoms may be, and have been, mistakenly ascribed to the effects of alcohol. Death ultimately results from shock, syncope, coma, or asphyxia; or, as in most cases, from various combinations of these conditions.

The *post-mortem appearances* in cases of death from cold are mainly a waxy anæmia of the surface, varied by bright-red patches on the more exposed parts of the body, and a corresponding congestion of internal organs, with extreme rigor mortis, very marked contraction of the external genitals, and over-distension of the bladder. The reddish-brown stains corresponding to the course of superficial blood-vessels are not pathognomonic of death from cold, but are a post-mortem change due to the physical effect of cold in disintegrating the blood-cells, and the subsequent diffusion of their colouring matter through the vascular walls.

Treatment.—The treatment demanded by cases of exposure to cold, whether the exposure have been moderate or severe, and whether the whole body or only a part have suffered, consists essentially in the *gradual* application of external warmth, and the equally gradual but effective restoration of the natural heat-producing power of the organism; and, as a broad rule, the less severe the exposure, the more quickly and energetically may artificial warmth be employed. In extreme cases, the sufferer should be promptly stripped of his clothing, wrapped in blankets or other woollen coverings, and placed in still, dry, cold air, as in a cold, empty room, the temperature of which is to be gradually raised as recovery proceeds. The surface should be stimulated by gentle friction, at first with snow or ice, and later with dry flannel or with the hands.

When practicable, the whole body may be at once immersed in a bath of ice-cold water, to which warm water is gradually added from time to time, while continuous hand-friction of the limbs and trunk is maintained. The bladder, if found to be distended, must be emptied by the catheter. So soon as the power of swallowing is restored, small quantities of warm fluids, such as tea, coffee, and beef-tea, may be administered; later on (but on no account at first), small quantities of wine or spirit, well diluted with warm water, may be given.

As consciousness returns, the sufferer may be placed in bed between the blankets, and the temperature of the room gradually raised. When the natural body-heat has been re-established, a nutritive enemata may be administered and a disposition to sleep encouraged. Serious cases are often followed, under the most favourable circumstances, by a tedious recovery; and rest, careful nourishment, and tonics are needed for a long time. In every case of extreme exposure the remedial measures indicated above should be resorted to with all possible expedition, and they should be steadily persevered in for a long time, however hopeless the restoration of vitality may at first appear.

As a *cause of disease*, immediate and remote, exposure to cold, and pre-eminently to damp cold, forms a most important factor in the death rate of this as of other countries with a temperate climate. There is scarcely any disease to which cold may not act as a potent predisposing cause; there is probably none whose severity is not aggravated by exposure, or in the course of which exposure to cold is not liable to set up intercurrent complications which the already enfeebled vitality of the patient may be powerless to resist.

C. E. SHELLY.

COLD, Therapeutics of.—As a therapeutic agent, cold commands an extensive field, and subserves various ends. These will be best appreciated by remembering that what is commonly called the "application of cold" is really the incidence of a sudden and transient physiological stimulus *plus* the physical "abstraction of heat," and that this latter may be slight or extreme, rapid or slow, limited and local or general and extensive, momentary, repeated, or continuous. The method employed, the area affected, and the duration of the process are the factors which chiefly determine the character of both the immediate and ultimate results.

The general effect of applying a good conductor at a low temperature to any part of the living body is to lower the temperature, to contract the blood-vessels, to diminish the nervous sensibility, and to lessen the bulk of the part. If the application be only temporary, its withdrawal may be followed by the restoration and local increase of vital activity, known as "reaction" (see COLD, EFFECTS OF). But if the application be longer continued, its physiological effects may

persist, and even continue to increase, after it has been withdrawn. Hence cold acts, both generally and locally, as an *antipyretic*; when moderate in degree, and followed by reaction, as a *tonic* and *stimulant*; it first excites, and finally abolishes, reflex action; it acts as a *sedative* to the vascular, cardiac, and nervous systems; as an *anodyne* and, in a more extreme degree, as an *anæsthetic*; locally as an *anaphrodisiac*; and when the system is under its influence the action of drugs is less rapid, less marked, and more uncertain.

The various methods of applying cold may now be briefly considered.

Affusion.—Cold affusion consists in the sudden application of a considerable volume of cold water to the whole or to some part of the body. It may be used in several forms. In the collapse sometimes observed in cases of high fever, where pulse and respiration fail, and the surface becomes cold although the internal temperature (as taken in the rectum) continues abnormally high, two or three gallons of water at 50° Fahr. may be poured over the patient, beneath whom a waterproof sheet has previously been placed; energetic reflex action is thus excited, the cardiac and respiratory functions are restored, the surface becomes warm, and the temperature in the rectum falls.

A stream of cold water may be similarly applied to the head of a robust child suffering from convulsions; to the throat and upper part of the chest during laryngeal spasm; to the head and neck in cases of sun-stroke, except when the skin is cold and clammy, with other evidences of greatly depressed vitality. Its powerful reflex action as a respiratory excitant makes the cold douche valuable in cases of threatened death from narcotic poisoning (*e.g.*, chloroform, opium, alcohol); and in like manner it has been found serviceable in exciting contraction of the uterus, the bowels, and the urinary bladder.

In hysteria and chorea and allied affections of the nervous system the cold douche and the shower-bath exert both a calmative and, by their tonic after-effects, a curative effect.

The cold douche is absolutely contraindicated in all cases of extreme weakness with feeble pulse, low muttering delirium, and cool, clammy skin.

Anæsthetic Uses of Cold.—Small superficial operations—such as the opening of abscesses, the insertion of sutures, and the removal of small tumours—may be

performed without pain upon parts which have been previously "frozen" by the application of a freezing mixture (salt and ice or snow, equal parts), or—more conveniently—by the ether spray. But the thawing of frozen tissues is apt to be attended with pain; and the value of this method of securing local anaesthesia has been greatly lessened since the discovery of cocaine.

Anodyne Effects of Cold.—The pain of inflamed surfaces, bruises, commencing abscesses, strained joints, &c., is often greatly relieved by the continuous application of cold. But in many instances experiment alone can decide whether cold or moist heat, in the form of a poultice, will be most comforting to the patient.

Baths.—For the methods and uses of the cold bath, see BATHS.

Compresses.—Two or three folds of absorbent material wrung out of iced water may be applied with benefit over painful regions—*e.g.*, to an inflamed throat, a bruised limb, &c. They must be applied directly to the skin, and should be frequently renewed—about every five minutes—in order to be really effective. If covered with oiled silk, and allowed to remain *in situ*, they soon act as tepid poultices.

Dry cold is usually applied by means of an india-rubber bag, or a bladder, filled with ice or snow, or a "freezing mixture." Ammonic chloride and potassic nitrate, of each 5 parts, mixed with 10 parts of water, will cause the thermometer to fall from 50° to 10° Fahr.; ammonic nitrate 1 part, snow 2 parts, and water 1 part will produce a reduction from 50° to 40° Fahr.; 2 parts of snow to 1 part common salt causes a fall from 32° to 4° Fahr.; and 5 parts of ammonic nitrate with 5 of common salt and 12 of snow or ice causes the mercury to sink from 18° above freezing point to 25° below it.

If a bladder be used, a fold of lint or flannel should be interposed between it and the skin, lest heat be too rapidly abstracted. When an ice-bag or ice-cap is applied to the head it should be suspended by means of a cord, so that it may not press unduly upon the part. Cold in this form has been applied with advantage for many hours and even days at a time, in cases of fracture, and in commencing vertebral caries, also to the eye after operations, to an inflamed testicle, over the ovarian region, to the throat in diphtheria, and to the shaven scalp in cases of meningeal and cerebral inflammation.

Dry cold is conveniently applied to many situations by means of Lieter's apparatus—in which cold water continuously circulates through the closely approximated bends of a small metal tube, which is sufficiently pliable to allow of the whole apparatus being moulded to the contour of the part on which it lies.

Douche—see *Affusion*, (*supra*).

Irrigation is a simple, ready, and valuable method of applying moderate cold continuously and without disturbance of the part to inflamed and injured joints, severe bruises, &c. Above the injured part a vessel containing cold water is fixed; some threads of worsted, or a piece of lamp-wick, well wetted, are so placed that while one end reaches to the bottom of the vessel, the other—and longer portion—falls over the edge and side of the vessel so as to siphon the water, drop by drop, on to the desired spot, whence it is conducted to a rubber sheet suitably disposed beneath the limb. The fluid may, of course, be variously medicated if so desired, and, by allowing it to flow through a tube from a reservoir of sufficient capacity, the rapidity with which heat is abstracted and the extent to which the part is "flushed" by the stream will both be increased. Injured joints have thus been irrigated with antiseptic solutions for weeks together, and with good results.

Injection.—Ice-cold water may be injected into the vagina or the rectum in order to stop severe hæmorrhage, but it appears to be less efficacious than very hot water. The practice of injecting a few drachms of cold water into the rectum after each action of the bowels affords much relief, and exerts a locally tonic and astringent action in cases of bleeding hæmorrhoids.

Lotions.—Cooling and evaporating lotions are applied to relieve local heat, pain, and swelling, and their influence tends to promote the absorption of extravasated blood. They are best applied by means of a single thickness of lint or rag saturated with the lotion and applied directly to the skin of the part. As soon as the lint begins to get dry or warm it should be removed, and another similar piece applied in its place; the greater the facilities afforded for evaporation from the lint, the more marked will be the cooling effect. In addition to cold water or vinegar and water, the following are effective cooling lotions:—Spirits of wine, or eau de Cologne (or other scent), and water; sp. vin.

rect. ʒvij in 1 pint of water; or the same with the addition of 5 or 6 drachms of potassic nitrate or ammoniac chloride; and ammoniac chloride ʒv, acid. acet. dil. ʒv, sp. vin. rect. ʒv, in 1 pint of water.

Pack.—The cold pack is a useful means of reducing the body temperature in cases of hyperpyrexia, or when, with high fever, violent delirium, much restlessness, and a hot, dry skin are present; but it is less efficacious than the cold bath. The patient is wrapped in a sheet previously wrung out of cold water; as the sheet becomes warm, it is replaced by a fresh cold one, or iced water may be squeezed over it from a sponge, or lumps of ice placed upon and around it. When the body temperature has been sufficiently reduced—or immediately on the appearance of any signs of collapse—the wet sheet should be removed, and replaced by a light covering, but not by a blanket.

In less severe cases the temperature may be appreciably reduced, and much comfort afforded to the patient, by repeatedly and regularly sponging the surface of the body with cold water, or toilet vinegar and water.

In addition to the several methods of applying cold externally, chips of ice slowly swallowed are often valuable in relieving inflamed conditions of the mouth and fauces and also in the treatment of nausea and irritability of the stomach. C. E. SHELLY.

COLIC, INTESTINAL.—Painful, irregular and spasmodic contraction of the intestine (not necessarily of the *colon*), unattended with fever.

Symptoms.—In a typical case the patient complains of severe—sometimes agonizing—paroxysmal pain of a twisting, gripping character, commonly at the outset referred to the region of the navel, and thence spreading to other parts of the abdomen. The belly is usually distended (except in **LEAD COLIC**, *q.v.*), but its muscles are subject to irregular contractions, and the varying outline of coils of distended and contracting intestine is visible through the abdominal walls. The pain is relieved by steady pressure and, temporarily at least, by the expulsion of flatus or feces. There is a general pallor and coldness of the surface and extremities, without pyrexia or increase in the rate of the pulse, which may even become feeble and slow. There may also be vomiting and diarrhoea, and severe cases are attended with great suffering and depression.

On the removal of the cause of the attack (*e.g.*, the expulsion of irritating ingesta) the paroxysmal pain usually gives place to some sense of general abdominal soreness; but occasionally it remains for some time unsubdued. The violent peristalsis occasionally results in enteritis or peritonitis, and is sometimes followed by a kind of catarrhal dysentery. An attack of colic is only very rarely fatal.

Intestinal colic is distinguished from a similar affection of the *stomach* by the site of the pain in the latter case being higher in the abdomen—about the ensiform cartilage—by the deeper percussion note elicited over the area of the distended stomach, and by the absence of the visible or palpable distension and contraction of the coils of intestine. In *rheumatism of the abdominal wall* it is the contraction of the muscles, and not that of the intestines, which causes the pain, the latter being much increased by palpation with the tips of the fingers. Special signs distinguish *Renal*, *Hepatic*, and *Lead Colic*.

Ætiology.—Painful spasm of the bowel may be caused by (a) irritation due to the nature and condition of the intestinal *contents*, such as the fermentation or decomposition of long-retained feces, fecal accumulations, undigested or irritating or partly decomposed food, by taking ices or cold drinks, by the presence of excess of or morbidly acid bile, of gall-stones, bundles of round worms, coils of tape-worms, or irritant poisons; (b) by morbid states of the *wall* of the bowel—adhesions, contractions, volvulus, strangulation, intussusception, local inflammation, ulceration, or occlusion, as by the pressure of neighbouring organs; (c) *reflex irritation* from other abdominal viscera—*e.g.*, the kidneys, liver, uterus, ovaries, or bladder—from sudden and violent emotion, from exposure to cold, particularly of the feet, legs, and lower part of the abdomen; (d) by certain forms of general *blood-poisoning*, as rheumatism, gout, or malaria, or the presence in the system of lead, arsenic, or copper.

Young, nervous, and excitable individuals—especially females—and those who lead sedentary lives and are subject to constipation, the gouty and rheumatic, and dwellers in malarial districts, are predisposed to attacks of colic. In hysterical females the attack is often attended—sometimes followed—by a marked degree of flatulence; and in some instances it is of an epileptiform character, and may be preceded by a

kind of *aura* in the shape of numbness, formication, or choreic movements of a limb.

Treatment.—Such causes of mechanical obstruction as a hernia, twist, adhesion, or local contraction of the bowel must be sought for, and, if possible, relieved without delay. Pain may be promptly alleviated, and the spasm allayed, by a subcutaneous injection of morphine; the effect of chloroform inhalation is less lasting, but when opium in any form is contra-indicated, inhalations of amyl-nitrite, or frequent drop-doses by the mouth, of a 1 per cent. solution are valuable. At the same time the bowel should be emptied of its irritant contents, which may be effected by a large warm-water enema, while a combined sedative and purgative is given by the mouth—*e.g.*, a grain of opium with 5 to 10 grains of calomel, or 20 grains of rhubarb, followed by repeated doses of a saline aperient with some carminative, until all irritant ingesta and all hardened and knotty feces have been evacuated.

The hot bath is always useful, and mustard or turpentine stupes, followed by hot fomentations sprinkled with landanum, or large light linseed poultices, are grateful to the patient. Sometimes steady friction with warm oil or opiate liniments gives the greatest relief at first. The diet should be restricted to liquids, including small quantities of stimulants if necessary; copious draughts of hot water are often of service both in relieving pain and in favouring evacuation of the bowel, as well as in checking vomiting when this exists.

The colic-like enteralgia of nervous women usually yields to 20-grain doses of sodium salicylate. Colic occurring in malarial subjects is best treated with quinine and arsenic. Generally speaking, during the attack aperients should be combined with sedatives.

Treatment subsequent to the attack must be mainly prophylactic in character. The diet must be properly regulated, a fair amount of daily exercise insisted on, and a regular and sufficient daily evacuation of the bowels secured by a suitable combination of laxative and tonic drugs until their natural and spontaneous action has been re-established. The patient should be instructed to wear a knitted woollen abdominal belt and warm woollen drawers and stockings.

C. E. SHELLY.

COMA has been defined as "a state in which insensibility or a defect of con-

sciousness is associated with a tendency to death, chiefly by asphyxia."

All degrees of it may be met with, from a mere impairment of mental and bodily power, up to complete insensibility, from which the person cannot be roused, paralysis of the voluntary muscles of the body being absolute and complete. In this extreme form the patient lies motionless, except for the movements of the chest, lips, and cheeks during respiration; the breathing is stertorous, foam accumulates at the mouth, the sphincters are relaxed, the pulse may be full and regular, the faec livid, the lips dusky, and the extremities cyanosed. The pupils are dilated and sluggish, or insensible to light, and the parallelism of the optic axes is lost. The eyes no longer move in concert, a slight degree of divergence will almost certainly be found, and one eye may remain stationary whilst the other is in motion, or they may move in opposite directions.

The *prognosis* in a case of absolute coma is always grave.

The *treatment* would depend entirely upon the cause. Coma is met with in such widely differing states as cerebral hæmorrhage, abscess or tumour of the brain, meningitis, sunstroke, epilepsy, diabetes, and uræmia (*see* CONSCIOUSNESS, DISORDERS OF).

COMA-VIGIL is the name applied to a peculiar condition, in which partial unconsciousness is associated with insomnia.

It is occasionally met with in the later stages of typhoid and typhus fevers and delirium tremens. The patient lies with his eyes wide open, but is insensible to all that goes on around him, although his appearance suggests that he is awake. The pupils are generally of natural size, but sluggish; the pulse is frequent, and the breathing free from stertor.

The *prognosis* is very unfavourable, the condition almost invariably ending in death.

COMEDONES.—A comedo is a minute elevation formed by the retention of sebum, epithelial cells, and small hairs in the distended efferent duct of a sebaceous gland, the protruding portion of which usually becomes blackish from the accumulation of atmospheric impurities.

A small mite—the *acarus* or *demodex folliculorum hominis*—is frequently found in the contents of the sebaceous follicles, but its presence is devoid of pathological significance. The *acarus* may be

seen under a low power of the microscope, after mixing the sebaceous matter with oil, and measures from $\frac{1}{12}$ to $\frac{1}{6}$ of a line in length; it has a distinct head, thorax, and abdomen, and four legs attached to each side of the thorax; it lies with its head directed towards the deepest part of the follicle.

The *distribution, general etiology, and treatment* of comedones are practically those of acne vulgaris, of which they constitute the first stage, and to which reference may be made.

CONIUM, Poisoning by.—Independent of poisoning by pharmacopœial preparations of conium, fatal accidents have occasionally occurred owing to the resemblance between the leaves of hemlock and those of parsley.

The *symptoms* of poisoning by hemlock are extreme weakness and numbness, commencing in the legs and spreading upwards; dryness of the mouth and throat, giddiness, impaired vision, paralysis of accommodation, dilated pupils, slowing of the pulse, and death from cardiac and respiratory paralysis, or from convulsions and coma.

Post-mortem Appearances.—These present nothing characteristic; there are the usual signs of asphyxia, and, when the leaves have been taken, a green pulpy mass may be found in the stomach.

Treatment.—This would be the same as that recommended for narcotic poisons (see OPIUM, POISONING BY). Tannin and astringents are especially recommended to neutralize the alkaloid as far as possible. Atropine in hypodermic injections ($\frac{1}{4}$ of a grain) may be tried as a stimulant to the cardiac and respiratory centres. Strong tea and brandy, ether, or ammonia are also useful.

CONSCIOUSNESS, Disorders of
—1. **Perversion of consciousness** occurs in the various forms of insanity, in the delirium of fever, in diseases of the brain, in meningitis, and in cases of poisoning by narcotic drugs.

Delirium may be divided into three forms—(1) *Low muttering delirium*, when the patient lies in a quiet condition, mutters to himself in a rambling fashion, and picks at the bed-clothes. (2) *Delirium tremens*, a result of alcoholic excess. In this form the patient is very restless and sleepless, has illusions and hallucinations, feels all manner of horrid animals creeping about him, is very suspicious, and keeps up a perpetual rambling conversation with himself; his movements are

tremulous, and occasionally he has violent outbursts of raving delirium. (3) *Raving delirium*, in which the patient is very violent, raves furiously, and exhibits tremendous strength for a considerable period. In such cases there is often a fixed delusion. Delirium is most common during the period intervening between wakefulness and sleep.

2. **Partial loss of consciousness** occurs in some forms of hysteria, in somnambulism, trance, hypnotism, and catalepsy. In this condition there appears to be a complete loss of recollection of sensory perceptions, and there is subsequently no remembrance of what happened to the patient during the state. Consciousness can usually be restored at once by the application of external stimuli. Motor actions are readily performed in an automatic fashion without causing any perception.

3. **Complete loss of consciousness** may occur from a variety of causes, which may be thus classified:—(1) Poisons from without, such as alcohol, ether, chloroform, opium, and other narcotics; (2) poisons from within, as in the uræmia of Bright's disease, and in the coma of diabetes; (3) asphyxia from any cause preventing access of air to the lungs and due aëration of the blood; (4) syncope from failure of the heart's action; (5) concussion or compression of the brain; (6) epilepsy; (7) apoplexy, from hæmorrhage into the brain substance, or blocking of the cerebral vessels by a thrombus or an embolus.

It will be useful to point out the *symptoms* by which the cause of the loss of consciousness may be determined. In some cases the *diagnosis* can be readily made; in others it is exceedingly difficult, and in some almost impossible.

(1) When loss of consciousness is caused by *poisons* from without, the onset is gradual, and there is often a history of the poison having been taken. The pupils are usually dilated and react to light, and the conjunctival reflex can be obtained unless the coma be very profound; but in opium poisoning the pupils are contracted to pin-point size. The patient can usually be roused by external stimulation. The presence of the odour of alcohol cannot be relied upon, as it may have been given after the onset of the symptoms for the purpose of restoring the patient. Violent struggling and the absence of convulsions are in favour of alcoholism, as opposed to apoplexy.

(2) In *uræmia* the urine contains albumen, but this is also frequently the case

in apoplexy. A peculiar "hissing" breathing is present, unlike the stertorous breathing of apoplexy. The patient can be aroused to answer questions, but immediately relapses into the previous drowsy condition. The onset is gradual in chronic nephritis, but in acute nephritis it may be sudden. A history of anasarca may be obtained, and also of general convulsive fits. The presence of albuminuric retinitis points to uræmia, but does not exclude apoplexy. The temperature is usually depressed, and does not tend to rise as in apoplexy. The face is pale. The pupils are equal, and may be either dilated or contracted; they react slowly to light. The pulse is often hard and tense.

(3) In unconsciousness due to *asphyxia* the diagnosis can usually be readily made from the history of the case, the marked cyanosis, the physical signs of the non-entrance of air into the lungs, and from the fact that, if the obstruction be not speedily removed, death ensues.

(4) In *syncope* the onset is sudden, the pulse is very feeble or imperceptible, there is extreme pallor of the face, the respirations are irregular and sighing, reflex action is usually preserved, and the sphincters are rarely relaxed.

(5) In *convulsion and compression* there is a history of an injury, or an actual fracture of the skull may be found.

(6) In loss of consciousness after an *epileptic fit* there is a history of a fit having occurred; the face is cyanotic, the breathing stertorous at first, but the stertor soon passes off; the pulse is rapid, the pupils are widely dilated, and do not react to light; the limbs are relaxed and the plantar reflex is abolished. There is often blood about the mouth, from the tongue having been bitten. The urine and feces are evacuated involuntarily. The urine does not contain albumen except after a rapid succession of fits. Many of these symptoms are present in apoplexy, but after an epileptic fit the patient usually recovers in from five to ten minutes, which is not the case in apoplexy. Immediately after an epileptic fit there is often conjugate deviation of the eyes to one side, but this passes off in from three to five minutes.

(7) In *apoplexy* the onset is sudden, the breathing is stertorous, the pupils may be unequal or dilated, and do not react well to light. The superficial reflexes are abolished either on one or on both sides. There is no failure of the heart's action. The limbs are relaxed, or there is rigidity on one side. The face

is suffused, and there may be a persistent conjugate deviation of the eyes and turning of the head to one side. Albumen may be present in the urine. If the attack begin with a fit the convulsions are frequently one-sided. It must be remembered that hæmorrhage into the pons Varolii produces contraction of the pupils similar to that found in opium poisoning. The temperature is depressed, but this is soon followed by a rise above normal, unless death ensue rapidly.

In dealing with cases of unconsciousness supposed to be due to drink, it is a wise rule, especially in hospital practice, *never* to send a patient away until he is so far recovered as to be able to walk and to give his name and address.

Feigned loss of consciousness is a favourite symptom with malingerers, and should not be overlooked; the diagnosis is assisted by observing that the pupils are equal, and react readily to light; that winking is produced by touching the conjunctiva or by suddenly aiming a blow at the open eye.

The *treatment* of the various diseases which may give rise to loss of consciousness will be found under their respective headings.

C. E. BEEVOR.

CONSTIPATION (Costiveness).—

An undue retention of feces, owing to delayed, infrequent, or imperfect evacuation of the bowels.

Individual peculiarity may render a considerable variation from the general rule of a daily evacuation not incompatible with the maintenance of health; but in constipation, whether the bowels be relieved only at abnormally long intervals of time, or more frequently but to an imperfect degree, there results a tendency to the accumulation of feces, with secondary consequences of a more or less noxious character.

The motions consist of a few small, hard, dry fecal lumps, or of large masses compacted of an agglomeration of such scybala, and sometimes smeared with mucus or streaked with blood. They are passed with difficulty, often with pain; they may be very dark or light and clay-like in colour, and are apt to be very offensive in odour. These hard motions may alternate with, or even be accompanied by, diarrhœa, a symptom of the intestinal irritation caused by the retained scybala; or, again, the patient may complain only of diarrhœa—frequent, painful, loose motions, attended with griping abdominal pains (*tormina colic*)—until

by appropriate treatment the retained faecal accumulations have been dislodged.

The most common sites of faecal accumulation are the caecum, the colon, the sigmoid flexure, and the pouches of a relaxed and distensible rectum. These masses may produce over-distension of the bowel, with consequent paresis and extreme atrophy of its walls; or, by more localized irritation, may beget sacculations, inflammation, ulceration, and perforation of the gut. They may accumulate, with the result of its complete occlusion; they can readily induce colic, catarrhal dysentery, and sometimes jaundice; and by the pressure which they exert upon the abdominal nerves and blood-vessels—especially on those within the pelvis—may give rise to congestion of the uterus and ovaries, with catarrhal leucorrhœa, menorrhagia, or metrorrhagia. Hemorrhoids, spermatorrhœa, and prostatitis, pain in the course of the great sciatic nerve, numbness and pain in the thighs, and coldness of the feet and legs may result from constipation.

Amongst the more remote, but frequently observed, effects of chronic constipation are anæmia, with a dingy sallowness of the skin; amenorrhœa, anorexia, headache (usually frontal), vertigo, nausea, flatulence, thirst, and lithæmia; foul tongue, foetid breath, lassitude; hypochondriasis and irritability of temper are also occasionally symptoms of this condition. These symptoms, being mainly attributable to a sort of general blood-poisoning by re-absorption from unduly retained faeces (and closely analogous to certain forms of sewer-gas poisoning), are sometimes grouped under the term **copræmia**.

Recent researches tend to show that these symptoms are probably manifestations of the toxic effect of animal alkaloids (ptomaines (*q.v.*) or leucomaines).

Ætiology.—The immediate causes of constipation are—(1) *Mechanical* obstruction of the lumen of some part of the intestinal canal; (2) *scantiness* or excessive dryness and hardness of the contents of the large bowel; (3) *paresis* of its muscular coat.

More precisely the causes may be distinguished as—(1) *Local*, including blocking of some part of the intestinal tube by accumulated scybala, faecal concretions, masses of round-worms, or by foreign bodies introduced by the mouth or per rectum; the development of polypi or other new growths; cicatricial contraction rigidity from in-

flammation, ulceration, carcinoma, or syphilis of some part of bowel-wall; enfeebled muscular contraction and atrophy of the bowel-wall resulting from prolonged over-distension of the gut with faeces or gas, or from inflammation, adhesion on lead-poisoning; also in cases of general enfeeblement and senile atrophy; pressure exerted by extra-intestinal tumours, especially on the rectum, as by a displaced or gravid uterus, by uterine fibroids, ovarian tumours, or enlarged prostate; enfeeblement of the abdominal muscles, by repeated pregnancy, or by obesity; a painful state of the abdominal walls, as in rheumatism, and conditions in which attempted defæcation provokes pain, such as inflamed piles, fissure of the anus, chronic dysentery, and the like; the reflex inhibition sometimes induced by painful and inflammatory states of the pelvic viscera.

(2) *General*, including depressed vital activity, as from anæmia or excessive venery; excessive muscular exercise or mental application or sedentary habits; the abuse of enemata and purgatives, neglect of the habit of regular defæcation, prolonged sleep; the use of certain articles of food, such as salt meat, cheese, tea; the abuse of opiates, tobacco, spirits; the imperfect clothing and undue exposure of the feet, legs, and lower abdomen, especially in young children; a dietary yielding too small a proportion of nutritive residue, or too scanty in amount—the result in either case being faeces too small in bulk to excite full intestinal peristalsis.

Constipation is apt to be a prominent symptom in certain diseases of the stomach, liver, heart, and nervous system; in some febrile conditions, in diabetes, during prolonged lactation, and after excessive perspiration or exhausting discharges.

Treatment.—The causes of mechanical obstruction or pressure and painful conditions of the anus, rectum, and of the abdominal walls must be removed or palliated. Habits of sloth and indolence must be amended, and regular open-air exercise, especially walking and riding, should be taken early in the day, while excess in muscular exertion, as well as in mental application, are avoided. A daily solicitation of the bowels at the same hour should be persevered in, however meagre the result may be at first, and the desire to defæcate should not be thwarted or resisted; nor should the act be unduly hurried over; its efficient

performance is much aided if the opening in the closet-seat be so narrowed laterally as to afford ample support to the buttocks—not merely to the thighs in front, as is usually the case. Regular friction and kneading of the abdomen over the course of the large bowel, beginning at the cæcum, may be practised with advantage. Early rising, immediately followed by a cold bath or the cold douche to the abdomen; the application of a cold-water abdominal compress; ample woollen clothing of the lower limbs and abdomen, and support of a pendulous belly by an appropriate belt or bandage; faradization of the abdominal walls, or the galvanic current with one pole in the rectum, are all useful measures in certain cases.

The diet should consist largely of green vegetables and of ripe fruit, and the latter may often be taken at or before breakfast with advantage; coffee rather than tea or cocoa at this meal, and a moderate allowance of light bitter ale or porter at luncheon or dinner, answer well in some instances. Coarse oatmeal porridge, brown bread, hominy, and fats should—when they can be digested—be taken in preference to fine white bread and starchy food-stuffs; a considerable amount of fluids—especially water, toast-and-water, home-made lemonade, aerated waters—may be taken. A tumblerful of hot water, slowly swallowed at bedtime, and one of *fresh* cold spring-water sipped while dressing, often prove effective in the milder class of cases.

On commencing treatment it may be requisite to soften and break up fecal accumulations in the rectum by enemata of oil or warm water, and even to remove them piecemeal by the scoop (or the handle of a large spoon). Should a second day pass without any evacuation, a small enema of cold water or of a drachm or two of glycerine may be used at the usual hour of defecation. A pipe or cigar after breakfast or dinner is effective in some cases.

Drugs are quite secondary to general hygienic and dietetic treatment, but their employment is often necessary. The object of medicinal treatment is to relieve pain or spasm of the bowel, as, for example, by a full dose of opium or of nuphar; to improve the tone of the muscular coat of the intestine, to exalt peristalsis, and to increase the flow of intestinal mucus. To this end several drugs may often usefully be combined—*e.g.*, a pill containing extr. aloes aquos. gr. j, pulv. rad. ipecac. gr. $\frac{1}{2}$, extr. nuc.

vom. and extr. belladonnæ aa gr. $\frac{1}{4}$, taken every night or every alternate night, and gradually relinquished; extr. cascarr. sagrad. gr. j to grs. iiij may advantageously replace the aloes in some cases. Rhubarb, colocynth, and podophyllin, with hyoscyamus or belladonna, are also of value; and a small quantity (gr. $\frac{1}{15}$ or gr. $\frac{1}{12}$) of calomel may frequently be added with advantage. In anæmia and debility, iron—especially the sulphate—arsenic, and quinine are indicated; iron is well given, combined with rhubarb and aloes, in pill; and in the constipation of amenorrhœa a teaspoonful of the confectio sulphuris every morning greatly aids the effective action of a ferruginous aperient taken over-night. Aloes is a drug generally unsuitable in cases of hæmorrhoids, and in congested or inflammatory conditions of the pelvic viscera, when the laxative electuaries are preferable. A dose of some effervescent saline laxative or of an aperient mineral water taken on rising is a useful adjuvant to other measures, but should not be relied on exclusively, or habitually taken for too long a period. A teaspoonful of the compound liquorice powder of the Prussian Pharmacopœia is generally useful. A few drops of syrup or of honey or of olive oil often act well in very young children; and a teaspoonful of olive oil, cod-liver oil, or castor oil every morning before breakfast suits some persons. When the secretion of bile is deficient, and after much bilious vomiting, pills containing 2 or 3 grains of dried ox-gall are valuable; nux vomica, belladonna, and small doses of carbolic acid are useful where flatulence is a troublesome symptom.

In treating constipation it is most important to avoid any approach to excessive or exhausting purgation; the bowels are first to be thoroughly relieved of distending fecal accumulations, and must then be strengthened and educated to do their own work unaided. As regards drugs, laxatives must be combined with intestinal tonics, and, as the normal function of the bowel is by degrees re-established, the aperient agent should be gradually withdrawn from the prescription, while the tonic ingredient may often be usefully continued for a considerable time.

C. E. SHELLY.

COPPER, Poisoning by.—All the salts of copper are, when taken in sufficient quantity, irritant poisons.

The prominent *symptoms* are a coppery

taste in the mouth, a sense of constriction in the throat, thirst, and pain and tenderness in the abdomen. Vomiting and retching soon set in, the vomited matters being blue or green; purging and tenesmus are also present, the stools sometimes containing blood. Jaundice, suppression of urine, and cramps in the extremities are amongst the later phenomena; the breathing is hurried and difficult, and the extremities cold. Death may ensue from coma or convulsions.

Post-mortem Appearances.—Inflammation of the mucous membrane of the alimentary canal is the chief change present; ulceration is rare; the liver may be fatty and friable; the cortex of the kidneys swollen and pale.

Treatment.—To get rid of the poison by the use of the stomach-pump and emetics is the first and chief indication; albuminous substances, such as white of egg, should be administered to render the poison inert. For the rest the treatment would be symptomatic, opiates or stimulants being used if necessary.

Chronic poisoning may result from the use of copper vessels in cooking, or from exposure to the effects of copper in certain trades. The chief *symptoms* are a general and increasing loss of power, colic, constipation, or diarrhoea and jaundice; retraction of the gums and a purple line along them have been described.

CORN (Clavus) and CALLOSITY.

—Intermittent pressure on, or friction of, yielding portions of skin causes hypertrophy of the horny layer of the cuticle, the rete Malpighii and subjacent papillæ being also somewhat inflamed and infiltrated.

Callosities thus produced constitute familiar "trade-marks" of various occupations (coachmen, oarsmen, smiths). A *corn* differs from the preceding form mainly in the involution and downward growth of the hypertrophied horny layer to form the so-called "root" in the centre, which, pressing upon the subjacent papillæ, either cause their inflammation or atrophy. The pain due to the pressure of this peg of tightly packed, hard epidermic cells upon the sensory nerves is either dull or exquisite, and often radiates widely, causing a feeling of extreme fatigue in the limb. It has lately been shown that the underlying sensory nerves undergo enlargement. Some corns, apparently from their hygroscopic properties, give rise to most pain in damp weather, the advent of which some-

times prophesy with unfailing certainty; while others cause most annoyance in dry and frosty weather. Corns are almost invariably produced by tight or badly fitting boots, the two conditions being often combined, and their commonest seats are the ball of the big toe, the outer side of the little toe, and the dorsal surface of the intervening toes. When situated between the toes, corns are "soft," owing to persistent maceration.

Treatment.—Callosities may be reduced, when expedient, by the prolonged application of a 10 per cent. solution of salicylic acid in ether, or of a simple ointment of salicylic acid of the same strength. Corns are best treated by prolonged soaking in hot water, subsequent shaving, and the excision of the "root." Many cases, however, yield to the persistent application of Unna's salicylic acid plaster-mulls, or to daily painting with a saturated solution of salicylic acid in flexible collodion. The innuonction every morning of a little soft soap is generally sufficient to prevent their recurrence, always provided that proper boots be worn. J. J. PRINGLE.

COUGH.—A cough is a violent and sudden expiration whereby the closed glottis is forced open, and any accumulated mucus in the larynx or trachea is expelled. A cough is generally a symptom of some affection of the lungs or respiratory tract, but it is also very often due to some morbid condition of the throat—e.g., enlarged tonsils, elongated uvula, or granular pharyngitis—and in a considerable number of cases it is of purely reflex origin, and depends on gastric irritation, disease of the ear, or other distant lesion. The *treatment* of cough is given under its various causes.

COUNTER-IRRITATION is a method of overcoming pain, inflammation, or other change in a part or organ by an effect produced on the skin in the immediate neighbourhood or at a distance.

There are three stages or forms of counter-irritation. In the mildest form, rubefaction is produced; in the next, vesication; and in the most severe, pustulation, or local destruction of tissue. Mustard is the best rubefacient. As a vesicant, nothing answers so well as the liquor epispasticus. A liniment of croton oil or antimony may be used to produce pustulation. By the use of the actual cautery, setons, and issues, still more severe and protracted changes are produced.

CRAMP.—A painful tonic spasm, especially liable to attack the muscles of the calf, occurring more often during the night than the day. It seldom lasts very long, but the pain is agonizing. Putting the extensor muscles into action, or grasping the thigh firmly, is the best means of relieving it. Some cause of irritation affecting the stomach or intestines will occasionally be found. It is met with in the subjects of chronic nephritis, and is also often an indication of a neurotic tendency. Not infrequently it is the forerunner of epilepsy.

CRANIOTABES.—An atrophy of the cranial bones occurring in infancy. The term is not, however, applied to a uniform thinning of any cranial bone. Shallow conical pits are seen at the necropsy, the wide part of the cone being on the inner surface. The pit is not smooth on the inside, but granular, and on the outer surface and around the margin may be seen a worm-eaten appearance, due to the presence of more or less osteophytic overgrowth. Possibly the bone is primarily the seat of a rarefying osteitis, and the softened bone atrophies from within from the combined effect of the weight of the brain and the counter-pressure or resistance of the pillow on which the child rolls its head. The seat of election of craniotabetic pits is the posterior inferior region of the parietal bone, but the superior part of the occipital bone, the temporal bones, the upper surface of the orbital plates of the frontal, and very rarely the upper parts of the frontals and parietals, may be affected. During life careful palpation and pressure may be needed to discover the wasted spots, as the pitting starts from within, and until it has nearly reached the external lamina pressure cannot indent the bone, and the so-called "parchment-crackling" is not obtained. The number of atrophic areas varies much in different cases. Mere marasmus is held not to cause this affection, but the writer cannot assent to this view; it is probable that rickets and syphilis are causative, but the relative influence of each factor must always be difficult to estimate. Frontal bossing is often more evident in those cases in which rachitic changes are present in the other parts of the skeleton, and when there are rachitic nervous symptoms. Craniotabetic spots are often associated with the soft vascular stage of Parrot's bosses—an argument in favour of the pathology (of the pits) above given. Some

observers, however, hold that there is a mere chemico-physical change in the bone, not a recognizable rarefying osteitis. Craniotabetic pits may be due to a premature formation of the markings of the convolutions on the inner face of the calvaria; they certainly almost invariably occupy the early formed convolution-impressions. The atrophic areas are seldom present at birth, but are common during the first months of life; they are less often seen after the tenth month, and are still more rare after sixteen months. That they are in some way associated with the rapid growth and development of the brain appears certain. Craniotables is a purely physical condition, entailing, as a rule, no risk to life, and causing no symptoms. Signs of rickets may be detected, and also those of syphilis; sometimes one, sometimes the other disease preponderates.

ANGEL MONEY.

CRETINISM, ENDEMIC.—Endemic cretinism is met with in various parts of the world, but is most common in the valleys of Switzerland, Savoy, Piedmont, and the Tyrol; it does not occur in Great Britain. The prominent features are a varying degree of idiocy, with arrested development, the subjects of the disease seldom reaching 5 feet in height. In a considerable proportion of the cases there is an enlargement of the thyroid gland. In places where cretinism is endemic, goitre is also endemic, and to a much greater degree; and it has been observed that when a family migrates to such a neighbourhood, some members of it will speedily become goitrous, but no cretins will appear amongst them for two or three generations. Children may become cretinoid if taken to live in one of these districts during the early period of development. The only constant factors known about these districts are that the soil is damp, and that it contains a large amount of magnesian limestone. Certain changes at the base of the skull, especially the premature ossification of the bones entering into its formation, have been regarded by Virchow as the cause of cretinism, but it would seem more probable that both these and the goitre own some further cause, and that, in some way not yet understood, the nature of the soil plays an important part in the causation of the disease. Removal to a more healthy district is the only measure available; it will at any rate prevent the children subsequently born from being cretins.

CRETINISM, SPORADIC — a congenital deficiency of intellect occurring with stunted development and other peculiarities.

Sporadic cretins may be easily recognized by their low stature—they are seldom more than 3 feet high, often less; by their large, flat-topped heads, pale, earthy complexions, and spade-like hands and feet. The hair is coarse, dry, and scanty, the skin rough and scurfy; the hands, feet, and eyelids are often puffy, and the extremities cold. The bridge of the nose is generally depressed, the mouth large, with thick lips and a large semi-protruding tongue. As a rule, the isthmus of the thyroid appears to be wanting, and the rings of the trachea can easily be felt. Very often soft pads, consisting of fat, can be perceived in the supra-clavicular spaces on either side. Development proceeds slowly: the anterior fontanelle may not be closed until the fifth year, or even later; dentition is delayed, and the teeth are apt to decay early; the long bones are stumpy and enlarged at their ends, and the hands and feet peculiarly square, with short fingers and toes; puberty is delayed. Cretins change very little as they grow older, and it is almost impossible to form even a guess at their age. The intelligence is very imperfect; it is seldom that they can even speak. As a rule they are good-tempered. Certain changes at the base of the skull have been found, but not the premature synostosis regarded by Virchow as the cause of endemic cretinism. The thyroid has been found to be absent on post-mortem examination. The analogy between this condition and myxœdema is most striking; the two diseases would appear to differ only in that the one is congenital and the other a disease of adult life. Sporadic cretinism has no relation with goitre, and is not hereditary. Cases have occurred where the mother has borne many children previously, and where she has borne few. Intoxication of the parents at the time of coitus has been suggested as a possible cause. It is equally common in the two sexes. The *treatment* would be the same as for other forms of idiocy in children.

CRISIS.—Febrile affections which end abruptly are said to terminate by crisis. The best example is acute pneumonia, in which disease the temperature, in uncomplicated cases, usually falls suddenly on or about the seventh day. Diseases which commence suddenly have

a tendency to end in a similar manner, whilst those in which the onset is gradual rarely terminate by crisis; the temperature chart in typhoid fever, for instance, hardly ever shows a well-marked "crisis." The belief that a critical evacuation may carry off a fever is no longer entertained.

CUPPING is a mode of drawing blood to the skin with a view to relieve internal inflammation or congestion. A cupping glass is a small bell-shaped glass capable of holding 3 or 4 ounces; the air in this having been rarefied by heat (preferably by setting alight a drop of methylated spirit placed in it), the glass is applied to the skin, taking care to avoid a bony prominence. As the glass cools, the skin will be forcibly drawn into it, and will at the same time become congested. The cup should be left on for a time varying from ten minutes to half an hour, according to the object desired, and then removed; this constitutes *dry cupping*. In *wet cupping*, previous to the application of the cup, the skin is cut in about a dozen places by means of a specially devised instrument with that number of little blades, arranged in two parallel rows close together, and constructed so as to cut to any depth that may be considered best. The cupping glass, when warmed as before and applied over this area, rapidly becomes filled with blood, and in this way several ounces of blood can be speedily abstracted. The number of cups to be applied in either form of cupping will depend upon the nature of the case.

Dry cupping is chiefly employed in inflammatory affections of the bronchi, lungs, or kidneys. The applications of wet cupping will be found under **VENE-SECTION**.

CYANOSIS is the blue livid tint which the skin presents in certain diseases. It is due to the presence in the capillary vessels of insufficiently oxygenated blood, but never to the admixture of arterial and venous blood. It is met with in cases of congenital malformation of the heart, in long-standing heart or lung disease, in suffocation, and locally when an important vein is obstructed or compressed.

CYSTOCELE is descent of the bladder, pushing before it the anterior vaginal wall through the vulval orifice. It is usually the first stage of uterine procidentia; for the ordinary course

of that affection is that the descending anterior vaginal wall drags after it the uterus, and the uterus the posterior vaginal wall. The anterior vaginal wall descends first, because it is the least supported part of the pelvic floor.

The *causes* of cystocele are allied to those of displacements in general—viz., deficiency of muscular tone, which is generally a result of lowered nervous energy, and overstrain of muscular and fibrous structures, leading to their stretching or rupture. Such a condition of the muscular and fibrous structures of the pelvis is a frequent result of parturition, and the nervous and muscular tone is often lowered by the mental, emotional, and physical strain of lactation and the care of young children. Hence cystocele is in the majority of cases a sequela of child-bearing. Cystocele, however, occasionally occurs in women who have not borne children. It is most often met with amongst those whose employment involves physical strain, and comparatively seldom in the well-to-do.

The *symptoms* are a feeling of weight, "bearing-down," and aching in the back, lower abdomen and thighs. The call to micturate occurs with undue frequency. The patient can feel a protrusion between the labia and, if it be large, she may find that she cannot empty the bladder until she has pressed this up. All the symptoms disappear when the patient is recumbent, and are aggravated by violent or prolonged exertion.

Diagnosis.—A swelling covered by mucous membrane can be seen presenting at the vulva and separating the labia. On vaginal examination this is found to be the anterior vaginal wall. A much curved sound passed into the urethra with its concavity backwards is felt to pass into this swelling.

Treatment.—If the symptoms be very slight, they may be relieved by medicines which restore depressed nervous tone, such as quinine and strychnine. If these

fail, local treatment will be needed. If the vaginal orifice be not much dilated, a vaginal pessary will afford relief. The best for this purpose is Hewitt's "cradle" pessary. The patient can be taught to take it out and replace it herself. A ring of watch-spring covered with india-rubber, or one of the varieties of Hodge's pessary, is also useful. These instruments the patient can remove, but cannot replace, because she cannot, except by accident, get its posterior arch behind the cervix. If one of these pessaries be used, it should be removed, the parts examined, and the pessary cleaned and replaced at least once in three months. While wearing it the patient should syringe the vagina with warm water night and morning; otherwise, especially if an india-rubber instrument be used, an offensive discharge may result. If the vaginal orifice be much dilated, no vaginal pessary will be retained. The choice then lies between a pessary supported by bands attached to a waist-belt—one of the many forms of cup and stem pessary—and an operation to contract the vagina. Such an operation should only be done in patients who have ceased bearing children. In some cases it will, without further treatment, remove the symptoms, but this only happens in the minority of cases. In most, however perfect the result seem to be a few weeks after the operation, the downward pressure of the anterior vaginal wall again dilates the artificially narrowed vaginal orifice, and the old state of things is reproduced. But the narrowing of the vaginal orifice will enable the patient to wear a vaginal pessary, and so do without the waist-belt and straps. A properly adjusted vaginal pessary does not itself press into the vaginal orifice, and will prevent the anterior vaginal wall from doing so. More than this cannot be promised with certainty as the result of operation.

G. E. HERMAN.

D

DEATH, MODES OF.—Failure of the heart or of the respiratory mechanism is always the ultimate cause of death, although in many cases the brain, pons, or medulla is the part primarily affected, the respiratory or cardiac centre being subsequently paralysed, death then occurring from *coma*. When

the failure of vital power is very gradual it may not be possible to determine whether death commenced at the heart or lungs; for example, in cancer affecting the alimentary canal, in cases of persistent diarrhoea or vomiting, and in other wasting disorders. Death occurring in this manner is said to be due to

asthenia. But in the majority of instances it can be readily determined whether death commenced at the heart or lungs, the former being the more common. *Syncope* is the term used to denote death from cardiac failure. It may be absolutely sudden, occurring either in ventricular systole or diastole, and due either to spasm or paralysis of the heart; in the one case the cavities are found empty; in the other, full of blood. Diseases of the heart, such as fatty or fibroid degeneration, or of the coronary arteries, valves, or aorta, are the chief causes of sudden death under this head. In this group may also be included sudden death from violent mental emotion, from drinking cold water when heated, from a sudden blow in the epigastrium, or severe injury to any part of the body—*i.e.*, from *shock*, however caused. In other cases the heart failure is more gradual, and is shown by faintness, giddiness, nausea, pallor, coldness, sweating, and dimness of sight; the pulse becomes rapid, feeble, and is finally extinguished, insensibility supervenes, and the heart's action ceases; the cavities of the heart will be found relaxed and more or less full of blood. Another form is death from loss of blood, as betrayed by extreme pallor, fainting, and delirium. After death the heart will be found contracted. In death from *collapse*, the heart sounds become feeble, the features sunken, but there are no subjective symptoms and no loss of consciousness; eventually, death is sudden. Death commencing at the lungs is from *asphyxia*. It may be sudden, owing to paralysis of the respiratory centre in the medulla, as in the case of certain brain diseases, especially those involving the base of the brain; or from the effect of certain poisons on the medulla, or from plugging of a branch of the pulmonary artery. The respiratory centre may be gradually paralysed in various ways by occlusion of the trachea or larynx, or from deficiency of oxygen in the respired air. In all cases of *asphyxia* the lungs and right side of the heart will be found engorged and the left side empty.

JOHN ABERCROMBIE.

DELUSION.—Delusions are false beliefs which affect the actions and manner of life, which appear incredible to persons in the same condition of life as the person who expresses them, which are not recognized on an appeal to reason, and which are the result of an abnormal condition of the brain. They must be distinguished from hallucina-

tions, which are sensations in the absence of external stimuli, and illusions, which are false perceptions of actual objects. Delusions may be systematized or unsystematized. The former are of serious prognostic import, and are best seen in cases of chronic insanity. Three chief varieties may be mentioned—(1) of imaginary greatness, (2) of secret agencies and persecution, (3) of suspicion. Systematized delusions are compatible *inter se*, generally incompatible with the laws of nature, and nearly always originate in sense-perversions. Unsystematized delusions, such as the fleeting delusions of general paralysis or mania *a potu*, occur in most cases of insanity, are of every conceivable variety, have little relation *inter se*, are generally perversions of possible or even actual facts, frequently do not depend upon disorders of the senses, and are the external expression of abnormal brain action or mere mental confusion.

G. T. REVINGTON.

DEMENTIA.—This term is used to designate acquired mental weakness, as distinguished from Amentia or congenital weak-mindedness.

Symptoms.—The prominent characteristics of dementia are loss of reasoning power and of the faculties of attention and origination, weakening of the powers of observation, imagination, memory, and volition, scantiness of the association of ideas, feebleness of the emotions, limited reaction to environment, partial loss of self-control, self-respect, and of regard for the decencies of life, and finally loss of the dominant human feelings—affection, hope, and ambition.

The only difficulty of *diagnosis* is the distinction between the temporary form of dementia, or secondary stupor as it is well called, which follows acute attacks, and is curable, and the incurable secondary dementia.

No *prognostic* characteristics can be as yet pointed out; each case must be judged separately, and apparently hopeless cases will occasionally recover, while cases with every favourable symptom end in dementia.

Varieties and Aetiology.—Dementia has been well described as “the goal of all the insanities,” and to get a complete grasp of this subject the reader must refer to the articles on the various diseases mentioned below.

The following varieties are usually described:—(1) Primary, (2) secondary, (3) senile, (4) organic, (5) alcoholic.

(1) *Primary dementia* is a misnomer,

and cases which fall under this head in current literature will here be treated with melancholia and the insanity of stupor.

(2) *Secondary, Sequential, or Terminal Dementia*.—This is the most typical form, and nearly always occurs after an acute attack, more frequently after mania than melancholia, and is the result of disease attacking a brain which is just attaining its highest development, and occurs, therefore, chiefly in the insanity of adolescence, from eighteen to twenty-five years of age. The dementia which results from acute attacks after the age of twenty-five is usually complicated with delusional or maniacal symptoms. The duration of the attack and the intensity of the symptoms have only a slight, if any, influence in determining the occurrence of dementia after the acute attack. Heredity is the great factor, and, the further knowledge advances, the more firmly is the opinion held that original brain constitution determines the progress of disease towards either recovery or dementia, whether that brain constitution be due to obvious heredity, to reversion, or be apparently adventitious. The characteristic features of secondary dementia, in addition to the general symptoms of dementia previously described, are the absence of motor symptoms, such as we find in congenital weak-mindedness or in general paralysis, the excellence of the bodily health as a rule, the capabilities of useful employment and the stationary character of the mental symptoms, which often remain unchanged for twenty or thirty years.

(3) *Senile Dementia*.—The insanities of the senile period will be treated separately. Their most striking characteristics are the marked tendency to end in weak-mindedness, the complication of the dementia by maniacal or melancholic symptoms, the marked eroticism, and the filthy habits.

(4) *Organic dementia* differs chiefly from the senile form in the causation, and includes all forms of weak-mindedness resulting from gross brain lesions, such as apoplexies, softenings, and tumours. Post-apoplectic dementia is the commonest form, and is generally a mild type of weak-mindedness.

(5) *Alcoholic Dementia*.—This form presents no special features distinguishing it from other forms of dementia, and is treated under the head of INSANITY, ALCOHOLIC.

Pathology.—The morbid anatomy of dementia cannot be separated from the

morbid anatomy of all chronic insanity. The general brain atrophy, the compensatory thickening of the brain membranes, and the excess of fluid in the meshes of the pia mater, the cellular degeneration, and the increase of neuroglia are common to all, and are probably more the result of long-continued disuse than the cause of the dementia. It is possible that dementia is the result of a lowering of function—that is to say, of changes as yet unrecognizable by our histological methods.

Treatment.—While secondary dementia will remain the typical form, all insanity tends to end in dementia. Every insanity is, in fact, a potential dementia, and, as has been well said, “the cardinal problem of psychiatry is to avert this tendency;” and when we consider that 40 per cent. of all fresh cases of insanity actually end in dementia, and that two-thirds of the total number of the insane are demented, we see what an important problem this is. The term dementia should be limited to the established and incurable forms, and treatment directed to the temporary dementia, better termed the secondary stupor, which supervenes on the cessation of the acute symptoms. The cardinal principles of this treatment should be attention to the bodily health, abundance of food, and employment in the open air, with, in some cases, the use of tonics, the cold shower-bath in summer, the Russian douche, electricity to the head, and possibly massage, and most emphatically the avoidance of narcotics.

G. T. REVINGTON.

DEMULCENTS are substances which are administered for their soothing effect on mucous membranes. Their action is probably mechanical. They are white of egg, starch, glycerine, gelatine, gum, honey, linseed tea, linseed, almond and olive oils.

DENTITION.—Any symptoms of illness occurring in an infant at or a little over six months of age should suggest the possibility of teething being the cause, and this applies also to somewhat older infants who have already cut some teeth, but not all. The troubles to which dentition may give rise are most varied. A febrile condition, fretfulness, disturbed sleep, convulsions, cough, or diarrhoea are the most common. A child is apt to present the same symptoms with each tooth. If the gum be swollen, hot, and tender, and of a dark colour, it is highly probable that a tooth is causing irrita-

tion, and lancing the gum in such a condition will often give relief, but, unless the tooth be nearly through, it is worse than useless to lance the gum, and some authorities are of opinion that the same may be said of the operation under any circumstances.

DEPLETION is the means whereby engorged blood-vessels are relieved of some of their contents. It is of two kinds, either general or local; of the former, venesection and purging are the most efficacious, the production of vomiting or sweating being less useful measures; whilst blood-letting by means of leeches, cupping, or scarification constitutes the local measures of depletion.

DERMATITIS is a convenient generic term used to designate an ill-defined and extensive group of symptomatic inflammations of the skin characterized clinically by redness, heat, swelling and pain, terminating in resolution, suppuration, gangrene, or chronic dermatitis. The distinction between dermatitis, erythema and eczema is a purely arbitrary one, based rather on causal than on clinical or anatomical differences. Thus, in all, the essential process is an erythema the further progress and development of which depend upon the duration, intensity and quality of the exciting cause and the physiological vitality or idiosyncrasy of the individual. The various grades of severity comprise the formation of erythematous patches, papules, vesicles, pustules, bullæ, and the occurrence of hæmorrhage and gangrene. J. J. PRINGLE.

DERMATITIS GANGRÆNOSA (*Sphaceloderma*) may be primary or secondary to other skin diseases. The primary form occurs most frequently in adults as the expression of special constitutional depravity, and is symmetrical in its distribution. The lesions are at first reddish or purplish erythematous spots, usually on the trunk and extremities, which vesicate, rapidly become gangrenous, and slough; they are attended by fever and constitutional disturbance. Spontaneous recovery generally ensues after a more or less prolonged period, each spot leaving a scar, but relapse is frequent. The condition presents many points of affinity with Raynaud's disease, diabetic gangrene, acute bed-sore, and to a form of gangrenous rash which sometimes accompanies acute cerebro-spinal meningitis.

It is closely simulated by the feigned

or artificial skin diseases produced by hysterical subjects or malingers. These are situated on the front of the chest, or more easily accessible portion of the limbs, generally on the left side, and are produced by scratching with the nails, the pressure of coins, or the application of caustic substances. They rapidly recover when the patient is carefully watched and the ulcers are protected by simple dressings.

The secondary form is most common in strumous and syphilitic children, and may succeed any antecedent pustular skin disease—*e.g.*, eczema, impetigo, vaccinia, and especially varicella (*V. gangrænosa*). The gangrenous patches may be numerous and extensive, accompanied by very high temperature, and death may rapidly ensue, or a series of minute pustules, each of which sloughs and leaves a scar, may appear in crops, and prolong the disease for an indefinite period. There is considerable presumptive evidence that the condition depends upon the presence of a specific micro-organism.

Occasionally the lesions are very trifling, but itching may be a troublesome symptom (*e.g.*, in varicella prurigo of Hutchinson).

In adults a similar ulcerative gangrenous action may affect spots of psoriasis and lichen ruber.

Treatment.—(1) *Constitutional.*—All tonic remedies are indicated, especially quinine and sulpho-carbolates, cod-liver oil being of special value in children. In many cases affecting adults opium proves invaluable.

(2) *Local.*—Any soothing ointments may be applied, the oleates of bismuth and zinc being perhaps the most generally useful. Dilute ammoniated mercury ointment is sometimes efficacious in children. J. J. PRINGLE.

DERMATITIS PAPILLOMATOSA CAPILLITII (*Acne Keloid, Sycosis Frambæesiformis*) is a rare form of chronic disease which affects the nape of the neck and adjacent portion of the scalp. The initial lesions consist of minute red papules, which occasionally suppurate, and are usually traversed by a hair. When pierced, a surprising amount of thin, mucoid discharge may emerge from these, as in cases of kerion. Ultimately the papules coalesce to form extensive, irregular, hard, white or reddish, keloid-looking growths, from which a few brush-like bundles of atrophied, but firmly adherent,

hairs protrude. Subsequently papillomatous tumours develop, which suppurate and break down, leaving extensive scars. Most described cases have occurred in males of middle age, and have caused little pain.

The growths consist of hypertrophied papillæ, with dilated blood-vessels, and infiltrated with leucocytes; subsequently fibrous tissue is formed. The development of papillomatous excrescences is by some authorities considered as accidental, while others consider the relationship with carcinoma as an intimate one.

Treatment consists in the destruction of the disease by caustics, or its removal by excision. J. J. PRINGLE.

DERMATITIS VENENATA is the result of the contact of irritating substances with the skin. The condition is common, as a chronic one, in many trades which necessitate the handling of noxious matters, or even the immersion of the hands and arms—the parts most frequently affected—in water. Grocers, bakers, bricklayers, colourmen, flax-spinners, French polishers, potmen and laundresses may be particularly instanced. A form of dermatitis (tar acne, *acne picealis*), which involves chiefly the extensor surfaces of the limbs; is common in fibre-dressers, who work with paraffine, and in persons otherwise brought in contact with preparations or vapours of tar or its congeners (creasote benzine, oil of cade, impure vaseline), in which the inflammation and blocking of the sebaceous follicles by dark comedones are prominent features. Aniline dyes employed to impart gaudy colouring to cheap flannel underclothing, acids, bichromate of potash, alkalis and arsenical preparations are all frequent causes of dermatitis. Many substances employed medicinally act in a similar manner—*e.g.*, those used as counter-irritants (croton oil, cantlarides, savin, tartar emetic, mezereon, turpentine, mustard); or as caustics (nitrate of silver, chloride of zinc); and occasionally carbolic acid, arnica, chrysarobin and mercurial ointments. A very severe form of acute general dermatitis is common in America, due to contact with, or even proximity to, different varieties of the botanical genus *Rhus* (poisonous sumach, poison ivy), the immediate causative agent being an exceedingly volatile acid which they contain.

Treatment must in every case be

directed to the cause. Soothing local applications alone are seldom efficacious. Protection of the exposed parts—*e.g.*, by india-rubber gloves—is always advantageous, but to secure permanent recovery it is often necessary for the patient to change his occupation.

J. J. PRINGLE.

DESQUAMATION is the process of shedding the skin seen during recovery from certain ailments. After scarlet fever the skin peels off in layers, and such a peeling in any person is always strongly suggestive of a recent attack of that malady. After measles there is often a branny desquamation.

DIABETES INSIPIDUS.—Under this term are included certain cases the leading symptoms of which are great thirst and the excessive secretion of urine free from sugar and of low specific gravity.

Symptoms.—The disease often commences suddenly after the occurrence of some injury or nervous shock. It may, however, be gradual in its onset, and it has been known to be congenital. The first symptom complained of is an excessive secretion of urine, though thirst very quickly ensues.

The urine is passed in large and sometimes in almost incredible quantities; 30, 40, and 50 pints a day are recorded. It is pale, almost colourless, and clear; its specific gravity ranges from that of water to a few points above this. The percentage of solid matters in the urine is greatly lowered, but the daily total excretion is in most cases increased. The urea is usually increased in amount; in some cases the phosphates and in other cases the chlorides have been excreted in excessive proportion, but ordinarily the normal ratio of the different solid matters remains undisturbed. Inosite has been discovered in the urine in several cases, but very rarely is albumen or any other foreign substance found.

Thirst is intense, and sometimes unquenchable, and it is to be noted that limitation of the fluids imbibed does not suffice to lower the excretion of urine to the normal. The tongue and mouth are in nearly all cases dry, but in a few instances an excessive secretion of saliva has been observed. The appetite is, as a rule, not increased, as is the case in diabetes mellitus; yet, again, it may in rare instances be voracious. The skin is dry and harsh, but boils, carbuncles, and pruritus are not observed.

In severe cases the general health is always affected. The patient emaciates greatly, becomes weak and languid, and complains of epigastric and other pains; the nervous system is disturbed, insomnia, irritability of temper and mental feebleness being symptoms of common occurrence. In other instances, again, the general health remains good, and the patient is only troubled by the thirst and frequency of micturition.

The *course* of the disease is very variable. Complete recovery may take place, but it does so in a small proportion of cases only. More commonly, a stationary condition is reached, and the patient may then, in the absence of complications, live for years, and even attain old age. On the other hand, the disease may gradually cause exhaustion, with failure of the heart and general œdema, and from this, or from the super-venition of phthisis or pneumonia, the patient at last dies.

The *duration* of the disease is as variable as its course. Some cases, especially those due to traumatism, are very rapid in their progress, whether towards death or recovery; others may last for many years. The occurrence of an acute febrile disorder not infrequently suspends, or for a time diminishes the intensity of, the affection.

Diagnosis.—The main symptoms are usually so pronounced as to render the diagnosis easy. It is necessary, however, to distinguish the disease from symptomatic and temporary polyuria, such as may follow excessive potations or the exhibition of diuretic drugs, and may also occur in hysteria and in convalescence from acute fevers. In this condition the thirst and emaciation of diabetes insipidus are absent.

Prognosis.—The small proportion of cases which end in recovery renders the prognosis in most instances unfavourable. The immediate gravity of the prognosis depends upon the extent to which the general health is affected, and the presence or absence of complications. The nutrition is least disturbed in those cases which arise after cerebral injuries, mental emotion, and acute febrile attacks, and in those which are congenital or occur in the very young without apparent cause. When phthisis or pneumonia has set in, and when the disorder is secondary to cerebral tumour or meningitis, the prognosis is necessarily most grave.

Pathology and Morbid Anatomy.—The disease shows a special association with lesions of the nervous system. In eleven

out of forty-two cases collected by Sir W. Roberts cerebral tumour or inflammation was found, not uniform in its localization; and Dr. Dickinson has recorded a case of diabetes insipidus associated with malignant disease of the solar plexus.

Unless the disease be a result of a gross lesion of the nervous system, as in the instances just mentioned, the morbid anatomy of the disorder reveals only lesions which are secondary to the excessive flow of urine and the marasmus. Thus, the kidneys have been found dilated and sacculated; in other cases they were enlarged and congested; and, again, they have contained multiple abscesses. Pneumonic or tubercular lesions of the lungs are frequently found, and may be the determining cause of death.

The proximate cause of the constant diuresis is a persistent dilatation of the blood-vessels of the kidneys. This, however, is itself a secondary condition, and is undoubtedly brought about through the vaso-motor system of nerves. The disease, therefore, can be caused by a lesion of the vaso-motor nerves in any part of their course, in the sympathetic system, in the spinal cord, in their centre in the fourth ventricle, or in the higher cerebral mechanism which communicates with the vaso-motor centre. The relation of gross nervous lesions to the disease is thus easily explained. Where such lesions are absent, we must assume that a functional disorder of the vaso-motor system exists, giving rise to the constant renal congestion. Bernard found that puncture of a certain spot in the floor of the fourth ventricle caused a copious secretion of urine which contained neither sugar nor albumen. In a few instances disease has localized this simple polyuric centre with a certain degree of exactness. Luys and Kien both found fatty degeneration of the nervous tissues in the floor of the fourth ventricle, and tumours in this situation have occasionally caused the disease. In three cases, recorded by Flatten, Gayet, and Kämutz, together with the polyuria, paralysis of the sixth nerves was observed, thus apparently localizing the lesion to the neighbourhood of the centre for these nerves. The writer also has recently observed a case in which, after an attack of meningitis, diabetes insipidus occurred, together with partial paralysis of both sixth nerves.

Ætiology.—Males are more often attacked than females. The disease may be congenital, but the largest number of cases commence between the ages of

five and thirty years. A well-marked hereditary tendency to the disorder has been sometimes observed. A syphilitic history has been noted occasionally. In a large number of cases no exciting cause whatever can be found; in some, however, the causal connection has been most close. Injury, and especially an injury to the head, exposure to cold, drinking cold fluids while heated, and an alcoholic debauch have been the most frequent determining causes of the disease. In a comparatively large proportion of cases the affection has ensued upon an acute febrile attack, while muscular effort and mental emotion have preceded a certain number of cases.

Treatment.—To limit the potations has no effect upon the disease, but greatly increases the distress of the patient. Valerian in large doses, given either as the powder or as the valerianate of zinc, has been apparently efficacious in some instances. Ergot also is highly spoken of by some writers. Nitrate of potash, nitro-muriatic acid, iodide of potassium, strychnine and pilocarpine have all been tried, and occasionally with success. Opium, while diminishing somewhat the thirst and diuresis, was found by Sir William Roberts to greatly aggravate the general discomfort. The constant current applied with one pole over the upper part of the spinal cord and the other over the loins or epigastrium has been used with success in a few cases. Attempts must be made to maintain the general health by tonics and nutritious food. The dryness of the skin can be relieved by warm baths, and the epigastric pain by warm and sedative fomentations. ROBERT MAGUIRE.

DIABETES MELLITUS. — By diabetes mellitus is understood a disease the main symptoms of which are marked and more or less persistent glycosuria, polyuria, thirst, debility and emaciation, and which has a tendency to a fatal issue.

Nevertheless, this, the type of diabetes mellitus, is united to simple glycosuria, a condition in which, although sugar is present in the urine, there is no serious or even observable departure from a state of health, by cases in which the patients, though in feeble health, are not conspicuously emaciated, but are distressed, rather than seriously endangered, by a diminished severity of the symptoms characteristic of the more grave disorder.

The condition above referred to as

simple glycosuria is described in the article on GLYCOSURIA.

Symptoms.—The onset of the disease is generally insidious. The patient's attention is only after some time directed to his state by experiencing great weakness or thirst, or possibly by frequent calls to urinate. Slowly the diabetic condition becomes more pronounced, the appetite is voracious, yet emaciation proceeds apace, the thirst is insatiable, the tongue becomes glazed, the skin dry and harsh, and an anxious and suffering appearance is impressed on the countenance. The urine still increases in quantity, its specific gravity rises, and the sugar contained in it is greater in amount. Occasionally the onset of the disease is sudden and its progress rapid, and in rare cases the symptoms may attain to a high degree of severity in even a few weeks. Unless the disease can be checked, the patient becomes still weaker, the circulation fails, and dropsy of the legs appears; finally, he dies from exhaustion, aided possibly by one of the complications which may arise at any stage.

Certain of these symptoms require fuller discussion.

The *urine* is greatly increased in quantity. The actual amount passed daily may vary from 5 to 6 pints, in very mild cases, to even as much as 25 to 30 pints, when the disease is severe. In the same patient, too, the amount of urine passed is variable. In the earlier stages of the disease the quantity is not greatly increased, and again as death approaches the excessive amount previously excreted is diminished. Similarly, too, less urine is passed when appropriate dietary rules are observed, and during an intercurrent febrile attack the total daily amount of urine may not exceed the normal. The quantity of urine is proportionate to the amount of fluid imbibed. Cases are exceptionally met with in which throughout the disease no very excessive amount of urine is passed.

Conditions similar to those just mentioned will also influence the percentage of sugar found in the urine, and during intercurrent febrile attacks the sugar has been observed to disappear completely. In addition, it must be mentioned that the amount of sugar is increased after meals, and markedly after the use of saccharine or amylaceous foods, while it is diminished by fasting. In mild cases, and in the earlier stages of severe cases the sugar may be

caused to disappear by abstention from sugar and starch in the diet; but in the later stages, and in all severe cases, its presence is persistent, though in diminished amount, in spite of a purely animal diet. The quantity of sugar is usually from 2 to 5 per cent., but may reach as high as 12 per cent. The total daily excretion of sugar ranges from 15 to 25 ounces, and it has been known to exceed 1000 grammes (= 2 lb.). The diabetic sugar gives the reactions of glucose, but levulose and inosite have also been found occasionally in small quantities. The specific gravity of the urine is increased; "it usually fluctuates a few degrees above or below 1040; it may rise to 1055 or 1060, or sink to 1015" (Sir Wm. Roberts). For the methods of testing the urine for sugar the reader is referred to the article on GLYCOSURIA.

The other constituents of the urine are increased as to their total daily excretion, though their percentage in the urine is diminished. Urea has been shown to be greatly increased. Uric acid may be deposited in reddish crystals, especially in the earlier stages of the disease. Teissier and, in this country, Dr. Ralfe, have drawn attention to cases in which the phosphates of the urine are greatly in excess, and sugar may or may not be simultaneously present. Yet all the symptoms of diabetes mellitus are found, and it has been proposed to term such cases "phosphatic diabetes." Leube has recently described glycogen as occurring in diabetic urine. The urine is usually very pale in colour when passed in excessive amounts, but of normal colour when the quantity is nearer the healthy standard. The spores and filaments of the yeast plant speedily develop in it when it is exposed to the air, and may form a whitish sediment. The reaction is faintly acid. Diabetic urine very often has a sweetish smell, resembling that of ripe apples. This is due to the presence of diacetic ether, which may be a product of β -oxy-butyric acid, also found in such urine, and may in turn give rise to the presence of acetone (acetonuria). Diacetic ether causes the so-called ferric chloride reaction of diabetic urine—viz., a purple red coloration when liq. ferri perchlor. is added to the urine in excess. The tests for these bodies are too complicated to mention here, and will be found described in the article upon URINE, EXAMINATION OF THE.

Thirst is one of the earliest symptoms

of diabetes: in most cases it is excessive, and may be almost unquenchable. The cause of the thirst is probably the presence of sugar in the blood, which needs large supplies of water to maintain it in solution and aid its transmission through the kidneys. The distress of the patient is greatly aggravated by any attempt to limit the quantity of fluid, but the excessive amount of fluid imbibed seems to increase metabolism, and so hastens the wasting of the body. It is to be noted that some patients complain but little of thirst, even though considerable quantities of sugar are passed; but the urine in such cases is seldom greatly increased in quantity.

An inordinate appetite is a frequent symptom of diabetes, but is more often absent than the sensation of thirst. Not infrequently in the course of the disease total disgust for food, or at least for such food as can be permitted, is experienced. The tongue is dry, red, and glazed, sometimes coated; the gums are prone to swell and bleed easily, and the teeth may become carious and drop out. In the later stages, apthous stomatitis is common. The saliva has often an acid reaction from the development of lactic acid. Digestive disturbances of various kinds are common, slight vomiting, flatulence, uneasy or even painful sensations at the epigastrium being frequently experienced. The bowels are as a rule confined, but towards the end of the disease obstinate diarrhoea may arise, and is to be regarded as a most unfavourable sign.

In the typical form of diabetes mellitus, *emaciation* is very pronounced, and rapid in its progress. All the tissues participate in the marasmus, the fatty constituents of the body being the first to disappear. The wasting persists in spite of the consumption of enormous quantities of food. Although much of the wasting is due to the profound changes in metabolism going on in the body, which will be mentioned in treating of the pathology of the disease, yet it is markedly controlled by the amount of fluid passing through the system, as indicated by the polyuria. When, under suitable treatment, the amount of urine is diminished until it nearly approaches the normal, the patient may not only cease to emaciate, but may even gain flesh. The pulse and respiration rates are usually normal, and, provided that no complications exist, the body temperature is usually below the normal. The sweet smell (acetone odour) mentioned above as

present in the urine is often perceived in the breath, and may be disagreeably intense. The skin as a rule is dry and harsh, but, on the other hand, abundant perspiration may be present throughout the course of the disease. The subcutaneous tissues are not infrequently œdematous. In the later stages of diabetes, the mental faculties fail to a pronounced degree. Not only are the mental processes carried on slowly, but there is great disinclination for mental exertion, and the temper becomes peculiarly irritable. Morally, too, a defect is noticeable, and patients, who in a state of health were notably truthful, will practise lying and deceit on the smallest provocation. The sexual powers tend to become abolished.

The symptoms described are those of the typical and most usual form of the disease. But cases are frequently met with which, while presenting individual symptoms of diabetes mellitus, do not show the complete picture described above. Thus, it is common to find that patients florid in complexion, and stout or even obese in habit, will pass large quantities of urine containing a considerable amount of sugar, and will complain of thirst. In such cases there may be a tendency to heart failure, and digestive disturbances are usually prominent. Yet no other symptoms of diabetes are observable, and emaciation may never ensue. A history of gout is to be obtained in many such cases, and copious deposits of uric acid may be found in the urine at times. This form of diabetes is prone to occur in the aged or middle-aged rather than in younger persons, who more often manifest the disease in its typical form.

Complications.—The complications of diabetes are numerous. Amongst the most frequent and serious are those which affect the lungs. That which is most usually met with is a chronic or subacute caseous pneumonia of tubercular origin. This begins by insidious infiltration of the apex, as is the custom with tubercular affections under other conditions, or may commence with ordinary pneumonic symptoms. It leads very rapidly to breaking down and excavation of the lung. Simple or non-tubercular pneumonia is also met with, and may be croupous or catarrhal in character. As a rule, it is acute in its course, but has been known to be chronic. All these inflammations of the lung in diabetes show a notable tendency to proceed to gangrene. It is a peculiar character-

istic, however, of diabetic gangrene of the lungs that the sputum and the breath have rarely the intensely fœtid odour which they present when no diabetes is present.

Numerous affections of the skin and underlying tissues are prone to occur in the course of the disease. Of these, boils and carbuncles are the most frequent, and have been long known to be of common occurrence in diabetic patients. Eczema and intolerable itching of the skin may torment the patient. These conditions occur in all parts of the body, but are most marked over the genital organs, and are especially frequent in patients of the female sex. Indeed, not infrequently the occurrence of pruritus, accompanied or not by an eczematous condition of the labia, is the first symptom of diabetes to attract the notice of the patient. Psoriasis and pemphigus may also be mentioned as rare complications of diabetes. Gangrene of the toes or of even greater portions of the lower extremities is not of uncommon occurrence, and usually resembles in character the dry gangrene found in old persons; its cause is, in most cases, obscure, but an obstruction of the arteries leading to the gangrenous part has been occasionally observed, and is probably due to sclerosis of the vessels.

Albuminuria is a common complication of diabetes, and may be due to a variety of conditions. It may result from a chronic irritation of the kidneys, set up by the passage of the saccharine urine through the glands. This leads in time to a sclerotic condition, with overgrowth of fibrous tissue, or to a chronic inflammation and fatty degeneration of these organs. In either case the complication has scarcely any influence upon the course of diabetes, and adds but little to the gravity of the prognosis. The same may be said when albuminuria, as occasionally happens, is the result of high pressure in the renal pelvis and tubes owing to the difficulty experienced in the transmission of the large quantity of urine into a hypertrophied and often distended bladder. But in certain conditions albuminuria is a grave phenomenon. It may be due to heart failure, and it may, again, accompany and even precede the most dangerous complication which can attack the diabetic—the so-called diabetic coma. When due to these causes, albuminuria is frequently the precursor of a fatal termination. Among minor complications which attack the urinary system may be mentioned pyelo-nephritis,

cystitis, urethritis, and, in the male, balanitis.

The cardiac failure so often observed in diabetes may be chronic in its progress, and apparently only a part of the general bodily weakness. The pulse becomes slow and feeble, and œdema of the limbs is prone to occur. It may, however, be acute in its onset and extreme in degree, and may give rise to most alarming symptoms, which are sometimes considered as constituting one variety of diabetic coma. Endocarditis has been observed in a few instances. In the digestive system, the only complication of importance is obstinate diarrhœa, which occurs sometimes as a late and often fatal trouble.

During recent years special attention has been paid to the numerous complications of diabetes which may arise in connection with the nervous system and its appendages. Defects of sight are common. That which has been most completely studied is opacity of the lens, or cataract. This occurs as a late symptom, and is generally considered an unfavourable indication as to the future duration of the case. It is of rapid course, and quickly affects both eyes. The cataract is most frequently of the soft variety. Its origin was at one time attributed to the direct action of saccharine fluid imbibed into the lens from the aqueous humour. Now, however, it is generally regarded as degenerative in nature, and as an indication of the low state of vitality of the tissues, other evidences of which condition are gangrene of the limbs and of the lungs. Operations for cataract in diabetes are seldom successful. Weakness of vision is also a common complaint amongst the sufferers from this disease. It is perhaps most frequently the result of a weakness of the muscles of the eye-ball, which interferes with accommodation. Such weakness may, in some cases lead to actual paralysis of one or more muscles, with strabismus and diplopia. Yet true amblyopia is of frequent occurrence, and in rare instances total blindness may ensue. Lesions have been observed, but they are not invariable, which explain the loss of sight, but it must suffice here to merely enumerate them—optic neuritis, retinitis, retinal hæmorrhages, retinal atrophy, and cloudiness of the vitreous. Iritis and keratitis sometimes occur.

Recently it has been observed that in many cases of diabetes the knee-jerk is wanting. This is a sign of a severe and

late phase of the disease, and its pathology is as yet obscure. It may be due to a peripheral neuritis, or to a generally depressed state of the spinal centres. Neuralgia affecting various nerves is extremely common in diabetic patients. Sciatica is thus a frequent symptom. On the other hand, however, diminution of sensibility is not unusual. Paralysis may affect individual groups of muscles, or may assume the form of hemiplegia.

But the most important and formidable complication which can affect the diabetic patient is **Coma**. This is a more common occurrence in young patients and in a comparatively early stage of the disorder, but those cases in which it appears are invariably severe. Often no exciting cause of this condition can be detected. Excessive muscular exercise, a mental shock, and the sudden assumption of an anti-diabetic diet have appeared to have a causal influence in bringing about the attack. The symptoms present themselves, as Dr. Dreschfeld has shown, in different groupings. Most frequently the patient complains for a little while of headache, epigastric uneasiness, nausea, or even vomiting. Then great restlessness and an anxious appearance are observed, which are soon followed by delirium and gradually deepening coma. A peculiar characteristic of the comatose state is an extreme dyspnœa affecting both phases of respiration, and styled by Kussmaul "air-hunger." There is no cyanosis, and no cause for the dyspnœa is revealed by physical examination of the chest. The muscles may twitch, but true convulsions are of very rare occurrence. The pulse is quick and feeble; the temperature is low. The pupils are usually, but not invariably, dilated. The urine is generally diminished in quantity and contains less sugar immediately before the attack than has been the rule in the preceding stages of the case. In the experience of the writer albuminuria is an invariable accompaniment and frequent precursor of the comatose state. The urine presents, in a marked degree, the sweet apple-like odour already described, and also gives the ferric chloride reaction. Moreover, when distilled after acidulation, acetone can be detected in the distillate by its usual tests, preferably by the addition first of liquor potassæ and then of a solution of iodine and iodide of potassium, when a precipitate of iodoform is produced. The breath also has the same odour, and has been shown to yield the same reaction of acetone when similar tests are applied.

Diarrhœa is occasionally observed in the comatose state, but there is more commonly constipation, and this, too, frequently precedes the attack.

In another form of diabetic coma the dyspnœa is not so marked, but there is drowsiness followed by gradually increasing coma. This condition is sometimes called the "apoplectic" form.

In a third class of these cases wild excitement is the more prominent symptom, and the condition may be mistaken for one of acute alcoholism. There may be, as additional sources of fallacy, a staggering gait and incoherence of speech. Soon, however, as in the preceding forms, drowsiness and coma supervene.

There is a fourth class of cases which is erroneously, but yet generally, included amongst the comatose forms, but is really the result of acute failure of the heart. Suddenly faintness is experienced, the pulse becomes rapid and feeble, pallor of the face and coldness of the skin are observed, and consciousness fails. In these cases the peculiar dyspnœa is wanting. All these forms of so-called diabetic coma are extremely dangerous to life, and recovery from them is of rare occurrence.

Morbid Anatomy.—No lesion has as yet been found in the bodies of diabetic patients which throws any light upon the nature of the disease. The liver, to which the attention is naturally first turned, has in the earlier stages been found enlarged and congested; in the later stages somewhat diminished in size and hardened. Microscopically, the liver cells may be quite normal, or may present minor digressions from the normal state. Glycogen has been demonstrated in their interior. The interstitial tissue is, in the late stages, increased in amount. Dr. Dickinson has described dilatation and congestion of the small portal vessels. The pancreas has been found hardened and atrophied. In the nervous system, also, Dr. Dickinson has described excavations in the white matter immediately surrounding the blood-vessels. The excavations may be empty or may contain remains of nerve matter and destroyed blood-corpuscles. These changes are found in both the brain and spinal cord. Other observers have, however, not found these changes so frequently as Dr. Dickinson has done, and it has been suggested that the appearances may be due to the mode of hardening the specimens. Spots of softening in various parts of the nervous

system are not uncommon. Sometimes, too, a gross lesion of the brain in the neighbourhood of the fourth ventricle, such as a tumour or hæmorrhage, may be found. In such a case the lesion has probably been the cause of the diabetic condition. The kidneys present lesions which have been already mentioned in discussing the albuminuria of diabetes. They may be sclerotic, or pale and fatty, or they may be distended, and, again, they may be congested. By suitable reagents the presence of glycogen has been demonstrated, especially in the cells of Henle's loops. In the kidneys of a patient dying from diabetic coma the cells of the convoluted tubes show the changes of coagulative necrosis. The cells are swollen, pale, and hyaline; they do not take staining fluids readily, and their nuclei are scarcely apparent.

The blood in diabetes is charged with sugar, and similarly sugar is found in all the fluids of the body. After death from diabetic coma, the blood has been found to be pale, more fluid than usual and to contain fat. Also, it gives off the peculiar sweet smell already mentioned, and on analysis has been found by various observers to contain acetone, di-acetic acid, di-acetic ether or β -oxybutyric acid. Probably the three first-mentioned bodies are products of decomposition of the fourth. Finally, the lesions due to complications are found in addition to those already described.

Ætiology and Pathology.—Diabetes is more common in males than in females, and more frequently attacks young adults and children than those more advanced in years. The milder form of diabetes which has been described is found for the most part in persons of middle age, and especially in those of obese habit. A gouty diathesis also favours the development of this form. An hereditary tendency to diabetes is frequently observed. Diabetes is more common in country districts than in towns. Persons of a neurotic temperament are found to be specially liable to the disease. Jews have been found to furnish a much larger proportion of patients than other races. Malaria, syphilis and pregnancy have been noted as predisposing causes. The exciting cause is frequently obscure. Exposure to cold, mental shock, injuries of the brain or peripheric nerves, and severe bodily exercise have preceded the outbreak of symptoms in some cases. Organic diseases of the brain, such as tumour, softening, and hæmorrhage, especially when affecting the region of

the fourth ventricle, are occasionally observed to be associated with polyuria and sometimes with glycosuria and other diabetic symptoms. The excessive use of starchy and saccharine foods, and the abuse of alcohol, will cause glycosuria and sometimes the more severe symptoms of diabetes, but such cases are generally easy of control.

A complete discussion of the *pathology* of diabetes would involve a consideration also of the views held with regard to the glycogenic function of the liver, and of the mass of arguments put forward by Bernard, Pavy, Seegen, Elstein, and others to support them. This would be far beyond the scope of the present article. All that can be attempted here is to give an outline of our present position, premising that, in spite of the careful attention and laborious research which have been devoted to the subject, the views of pathologists are as yet far from agreement.

The liver has for one of its functions the transformation of certain of the food stuffs into glycogen, a starchy material easily convertible into sugar by the action of ferments. All observers are agreed that the sugar absorbed from the alimentary canal is stopped by the liver, changed into glycogen, and so, at any rate for a time, prevented from reaching the circulation. Bernard believed that during healthy life the liver glycogen was being continually converted into sugar, and in this form carried off into the circulation to be used for the needs of the economy. Dr. Pavy, however, is of opinion that during health no such conversion takes place; that the function of the liver is not to convert the glycogen into sugar, but to prevent sugar reaching the circulation. In disease, however, the hepatic glycogen is, according to the latter view, abnormally converted into sugar: according to the former view, converted in greatly increased quantities. This excessive conversion of glycogen is believed to be due to a greatly increased flow of blood through the liver, whereby an excess of sugar is carried off, and a greater than normal quantity of arterialized blood is brought to that organ, such blood having been shown to possess great power of converting glycogen into sugar. In slight cases of diabetes, therefore, it is possible that, the liver having lost the power of transforming sugar into glycogen, the sugar passes on into the blood and is excreted by the kidneys, whilst, in more severe cases, dilatation of

the vessels of the liver, brought about by means of the vaso-motor system of nerves, leads to a greater supply of arterial blood to that organ, the result being an increased formation of sugar. The connection of glycosuria with diseases of the nervous system and with experimental puncture of the floor of the fourth ventricle is thus explained.

But the important and extended observations of Seegen have thrown new light upon the liver function. He confirms Bernard's view that sugar is continually being formed in the liver during health and poured out into the circulation. He also shows that amylaceous and saccharine foods are converted in the liver into glycogen. But he concludes that the glycogen of the liver takes no part in the sugar formation; that, in fact, the liver during life is constantly forming sugar out of the peptones absorbed from the alimentary canal. Diabetes is, according to this view, in its severe forms due to an increase of the destructive power of the liver upon proteids, a fact which goes far to explain the ravenous appetite and emaciation of diabetic patients; in its milder forms the liver function of converting sugar into glycogen is in abeyance, and the sugar obtains access to the general circulation in quantities too large for the organism to deal with.

Recent observations of Dr. Mitchell Bruce are of great importance, and tend to support Seegen's views. He concluded, from observations upon a marked case of diabetes, that (1) the diabetes was not due to mere transportation of sugar from the intestine, for, on removal of all saccharine and amylaceous materials from the diet, the patient still excreted 4000 grains of sugar a day, and that therefore the liver formed the sugar from nitrogenous materials. (2) Dr. Bruce observed that the glycosuria was controlled by morphine, but less so when the morphine was introduced subcutaneously than when given by the mouth, the conclusion being that the glycosuria was not due to a diminished destruction of sugar in the system, but to an increased influx of sugar into the blood. (3) He came to the conclusion that the excessive glycogenesis took place in the liver and not in the muscles and other viscera, because the administration of morphine reduced the sugar excretion, when it was introduced into the stomach and absorbed by the portal vein, even though the quantity used was insufficient to affect the nervous system, whereas

a larger dose, sufficient to affect the nervous system profoundly, when administered subcutaneously had but little effect upon the sugar excretion. (4) Dr. Bruce's final conclusion is that the seat of the disordered process, whatever may be its nature, is in the liver.

It has also been thought that some forms of diabetes are due to an inability of the system to use up the sugar. Dr. Rees asserted that diabetic sugar was not so easily oxidized as ordinary glucose, and Pettenkofer and Voit showed that diabetic patients absorbed less oxygen from the air and gave off less carbonic anhydride and watery vapour than healthy persons. These, however, are insufficient supports for such a theory.

Ebstein has formulated an original conception of the pathology of diabetes which, as yet, has received no support. According to his views, carbonic acid has the power of inhibiting the action of diastasic ferments, especially their action upon glycogen. Diabetes, he believes, is due to a defect of the protoplasm of the various tissues, by which too little CO_2 is produced. The glycogen of the body, in whatever situation it may be, is thus left exposed to the uninhibited action of diastasic ferments, and sugar formation consequently becomes excessive.

The pathology of diabetic coma is similarly obscure. The views held may shortly be summarized thus:—It is very generally believed to be due to a poison which circulates in the blood, but the nature of the poison is still a matter of dispute. It has been asserted to be acetone, di-acetic acid, or di-acetic ether, and the presence of all these bodies can be demonstrated in the blood by suitable methods. The researches, however, of Stadelmann would show that these substances are merely decomposition products of another body, which is probably β -oxybutyric acid, and that this is the true poisonous agent. It should be noted here that Dr. Ralfe had previously expressed the view that the symptoms of diabetic coma were those of an acid intoxication. Other theories which have been held are that fat embolism in various parts would account for the condition. Fat has been demonstrated in the blood, and fatty embolisms found in the lungs of patients who died of diabetic coma. Yet this does not explain the whole symptomatology. Similarly, the opinion that heart failure is the cause of diabetic coma, while true of certain cases, will not apply to all.

Course.—The progress, like the commencement, of diabetes is essentially gradual in the majority of cases. The typical cases last from one to three years, yet sometimes the disease is most rapid in its progress. Sometimes, too, after a sudden onset and rapid course for a short time, the symptoms abate in severity, and then assume the chronic course, which most commonly characterizes the disorder. While, as a rule, the disease steadily progresses towards the fatal end, cases occasionally happen in which intermissions are observed after the symptoms have been sufficiently marked and constant to remove all doubt as to the nature of the disease, but, as a rule, the more severe symptoms soon recur. Although, as already stated, recovery may occur in the milder forms of diabetes, the majority of well-marked cases die, the end being usually hastened by the presence of one or other of the complications which have been mentioned, and seldom due to simple exhaustion from the original disease.

Diagnosis.—The diagnosis of diabetes is rarely difficult. Nevertheless, it must be remembered that every case of glycosuria is not necessarily one of diabetes. Before the diagnosis can be considered as established it must be ascertained that the glycosuria is not a temporary condition only, that the urine contains more than a mere trace of sugar, and that some of the constitutional symptoms of diabetes are present.

Prognosis.—If the glycosuria occur in a patient of middle age, or at a later period of life; if there be a history of gout; if the patient be obese; and if the thirst, polyuria and other constitutional symptoms of diabetes be but slight, the prognosis is favourable. On the other hand, those cases in which emaciation is marked and rapid in its advance, and the constitutional symptoms are severe, only admit of an unfavourable opinion as to their issue. The results of treatment give an indication as to the further progress of the case, for when, on the assumption of an animal diet, the sugar disappears from the urine or becomes greatly diminished in quantity, and the polyuria lessens, it is probable that the case is not of a severe type, or is at least in an early stage. When, however, after all starchy and saccharine food-stuffs have been withdrawn, there is but little amelioration of the condition of the patient, the prognosis is very gloomy. The younger the patient the less likely is he to recover. Those cases, too, in which

some definite cause of the diabetes can be traced are more favourable than those in which the cause is obscure, provided, obviously, that the ascertained cause is not an organic lesion of the nervous system fatal in itself. The presence of the various complications above enumerated increases the fatal tendency of the disease. Attention may, however, be called to what has already been said as to the varying influence of albuminuria upon the progress of the diabetes according to the condition which gives rise to it. So few cases of diabetic coma have been known to recover that a fatal prognosis must almost necessarily be given when this complication presents itself.

Treatment.—It will be gathered, from the sketch of the pathology of diabetes which has been given, that the first effort of the physician must be directed to limiting the supplies from which the body may obtain or manufacture sugar. In the milder cases this will suffice to cure the disorder; in all but the very severe forms it will mitigate the symptoms and diminish the patient's distress. It is true that in severe forms of diabetes the liver has the power of transforming proteid matters into sugar, but to remove from the dictary those foods which contain starch or sugar nearly always lessens the amount of sugar which appears in the urine, and diminishes the amount of urine excreted. Strict directions must, therefore, in all cases be given to the patients to eschew those food-stuffs which contain sugar or starch. Nearly all animal foods, fish, meat, and fowl, may be permitted to the patient. Liver, however, is to be forbidden on account of the large amount of glycogen and sugar it contains, and similarly all molluscs are to be avoided, since the greater portion of their bodies is made up of liver. Cheese, butter, oil, including cod-liver oil, and eggs may be partaken of freely. Cream also may be allowed. Theoretically, milk should be harmful, but practically, if partaken of sparingly, it does no harm. Soups if not thickened with flour, and jellies if not sweetened with sugar, may be allowed. It is among the vegetable foods, however, that the greatest care is necessary in order to avoid those which contain starch and sugar. Bread forms such a large portion of an ordinary diet that its deprivation is one of the most severe hardships which must be inflicted on the diabetic. Yet it must be forbidden

entirely. Several substitutes have been suggested. Freshly made gluten bread is very generally used by diabetics. But much of the gluten bread sold contains a considerable quantity of starch, so that, if used at all, it should be obtained from well-known firms, such as Blatchley, Bonthron, or Van Abbott. Gluten flour, too, may be used as a thickening for soups. Bran cakes are another substitute for bread, and have the merit of being less expensive than the gluten preparations. Almond cakes, as devised by Dr. Pavy, are admissible, but are too costly for any but wealthy patients. The patient sometimes becomes disgusted with all these preparations, and it is then advisable to allow a small quantity of bread which has been toasted almost to a cinder. Sugar, of course, is to be forbidden, and with it, honey. Glycerine in small quantities may be used as a sweetening agent, or, again, the tabloids of saccharine recently introduced. In the writer's experience, however, saccharine has not been of so much use in diabetes as was expected. The patient, after its use, frequently complains of everything tasting sweet. Moreover, the diabetic does not crave for sugar as he does for bread, and soon becomes indifferent to its absence. Flour preparations, such as macaroni and vermicelli, potatoes, rice, sago, tapioca, arrowroot, peas, beans, carrots, beetroot, and parsnips, must be forbidden. Green vegetables, such as spinach, greens, turnip tops, lettuce, and watercress, may be eaten. Others, too, which contain a little sugar, such as asparagus, cauliflower, and cabbage, may be eaten if they have been previously boiled in a large quantity of water. Sweet fruits are to be avoided. Tea and coffee may be drunk, but no sugar must be added. Only a moderate quantity of alcohol can be permitted, and that must be taken in an unsweetened state. Sweet wines, liqueurs, and mild ales must be forbidden, but the patient may drink sparingly of bitter ale, dry sherry, claret, and whisky.

The patient must be clad warmly, so as to avoid all chills. Thirst may be allayed by acid drinks, the dilute phosphoric acid being specially useful for this purpose.

Many drugs have been lauded for their efficacy in diminishing the sugar excretion in diabetes, but of these a few only are of real service to the sufferer from this disease. Opium is of great value in diabetes, not merely for its anodyne effect, but for an actual curative influ-

ence upon the disease. Dr. Mitchell Bruce has shown that the best method of administering it is in the form of morphine, and by the mouth rather than subcutaneously. Dr. Pavy considers codeia to be preferable, in that it disturbs the digestion to a less degree than does the more powerful alkaloid. It is notable that diabetic patients exhibit a great tolerance of opium and its alkaloids.

Salicylate of soda has been found of use by many physicians, including the writer. During its administration, thirst and general discomfort have been alleviated, though no other positive effect on the disease has been apparent. A warning may be here given that the ferric-chloride test of the urine mentioned above cannot be used if the patient be taking salicylate of soda.

The general health must be maintained by tonics, such as quinine, strychnine, iron and cod-liver oil. Distressing symptoms should be treated on general principles as they arise. The bowels must be maintained in a state of daily activity by mild aperients or by small doses of the purgative mineral waters. Sir William Roberts recommends for the relief of the craving for food, and for the uneasy sinking sensation at the epigastrium, a pill containing 2 or 3 grains of assafœtida. Concerning other drugs which have been recommended, such as the bromides, arsenic in different combinations, belladonna, iodoform, lactic acid, and peroxide of hydrogen, it can only be said that, while individual physicians have written in high terms of them, the majority who have tried them have found them useless.

In diabetic coma treatment is of scarcely any avail. When preliminary symptoms are observed, smart purgation is recommended as a possible means of warding off the attack. During the attack good results have been recorded from transfusion of blood and from the injection of saline solutions into the blood-vessels.

A residence for a time at certain spas has been found of service in diabetes, and especially in those cases which are associated with a gouty diathesis. Carlsbad and Vichy are those most visited.

ROBERT MAGUIRE.

DIAPHORETICS are remedies which increase perspiration. They act in several ways—some by augmenting the flow of blood through the skin, others by direct stimulation of its afferent thermic nerves. Warm baths, the Turkish

bath, extra clothing, and alcohol act in one or other or both of these ways. Hot drinks stimulate the efferent nerves reflexly. Nicotine, opium, chloral, ether, chloroform, and alcohol act directly on the sweat centre. Pilocarpine acts especially on the peripheral nerves at their terminations in the sweat glands. Salines—*e.g.*, citrate and acetate of ammonium—probably stimulate the secreting cells of the sweat glands; whilst the mode of action of antimony, ipecacuanha, senega, and guaiacum is quite unknown. Substances which cause very profuse sweating are called sudorifics.

DIARRHŒA, ACUTE, FROM INGESTA.

Acute diarrhœa is the most prominent symptom of illness produced by eating articles of food which are undergoing certain peculiar processes probably allied to putrefaction. Milk, ham, pork pies, veal, fish, and sausages have been known to produce severe illness. Although not yet thoroughly worked out, it is clear that the ætiology and pathology of the affection vary much in different cases. Clinically, two classes may be formed—(*a*) in which the symptoms come on very soon (half an hour to a few hours) after taking the food, and are probably due to the presence in it of a chemical poison; (*b*) in which the symptoms set in after an interval of twenty or thirty hours or even several days. In the first class of cases the diarrhœa is profuse, watery, dark, and offensive. It is preceded by vomiting and acute abdominal pain, and accompanied by chilliness, a feeble pulse, a sub-normal temperature, great prostration, and sometimes by hallucinations. The tongue is furred; headache is not a prominent symptom. The amount of collapse is in proportion to the severity of the diarrhœa. In fatal cases, which are rare, death is due either to collapse or to the occurrence of complications. The chief signs observed after death have been gastro-enteric catarrh and congestion of the lungs, spleen, and kidneys.

In the second class of cases, where the interval between ingestion and the onset of symptoms is longer, the diarrhœa has the same characters, but is less easily controlled. Headache is a prominent and early symptom, vomiting is less marked, the tongue is thickly coated, but the tip and edges are red, the pulse is hurried, the diarrhœa is accompanied by great pain, and quickly produces prostration and cold sweats. Death may occur in this stage, but it is rare, the patient

generally passing into a condition of reaction, during which there is marked fever. Pneumonia is common, and parenchymatous nephritis may occur. Cases of this class are apparently due to infection by bacilli, which are also pathogenic to dogs and other animals.

Treatment.—The diarrhœa is, as a rule, comparatively easily controlled, a dose of castor oil, followed by a mixture containing bismuth and opium, or opium with rhubarb and other carminatives, being generally sufficient to check it. For a week or more after the cessation of the attack the patient is liable to a relapse should he commit any indiscretion in diet.

DAWSON WILLIAMS.

DIARRHŒA, ACUTE SUMMER.—This term is usually applied to acute attacks of profuse watery diarrhœa. Some of the cases are examples of diarrhœa from ingesta; others depend on the same ætiological conditions as cholera infantum (*q.v.*). The onset is usually sudden, colic being rapidly followed by very numerous stools, which retain a feculent character. A sinking sensation at the epigastrium, chilliness and general depression are always present, and in weakly persons may cause severe prostration.

The *treatment* is best begun with a large dose of castor oil with or without opium, if the case be seen early; at a later stage a mixture containing sulphuric acid, tincture of capsicum and a small quantity of opium, or a mixture containing small doses of castor oil (℥x-xx) and opium, or one containing chalk and catechu, or aromatic chalk with rhubarb and compound tincture of cardamoms is generally efficient. Abstinence from solid food and milk, and in bad cases confinement to bed, are important measures in treatment.

DAWSON WILLIAMS.

DIARRHŒA, CHOLERAIC.—This term has been used in various senses: it has been limited to diarrhœa occurring during the prevalence of cholera Asiatica, with which it has been supposed to have some premonitory or other relation. It has been extended to include every form of severe diarrhœa of sudden onset not easily traceable to any recognized cause. The pathology and ætiology of acute summer diarrhœa, of acute diarrhœa from ingesta, of cholera nostras and of cholera infantum are at present in a very unsettled state; they are discussed under their various headings.

DIARRHŒA, CHRONIC TROPICAL, the “hill-diarrhœa” or “white-flux” of India, the “diarrhœe endémique de Cochinchine,” is a severe form of chronic intestinal catarrh.

The earliest *symptom* is slight diarrhœa of a bilious character; the stools gradually become copious, light, and frothy, the tongue is sore, and there is progressive loss of strength. The changes in the tongue are especially characteristic; it is red, glazed and the papilla cannot be distinguished; painful ulceration of the tongue, lips and mouth generally follows; in extreme cases the mouth and tongue may be covered with an aphthous exudation. Subcutaneous fat disappears, the eyes sink, and all mucous membranes become blanched. Appetite is to a great extent retained, but the white frothy stools contain the undigested food. Unless there be a distinct malarial complication the temperature becomes subnormal. Albuminuria and œdema of the extremities occur at a late stage, and death is brought about by exhaustion.

The condition is to be *diagnosed* chiefly from chronic dysentery and from diarrhœa due to albuminuria or other causes; in distinguishing it from the former the history of the gradual onset, and in both the character of the stools—“the white-flux”—are of greatest value; only occasionally are the stools blood-stained.

The *morbid anatomy* of the disease is, in its early stage, a catarrhal inflammation leading to limited ulceration; in a later stage all the coats of the bowel become so wasted that it is transparent. The mucous membrane and solitary follicles may undergo albuminoid degeneration.

Pathologically the disease is allied to dysentery, but differs from it in its milder and more chronic course, in the more general affection of the whole intestinal mucous membrane, in the tendency towards wasting of the mucous membrane rather than to thickening, in the general absence of chronic ulceration even in the large intestine and in its greater amenability to treatment than chronic dysentery. The absence of any trace of bilious coloration of the stools has suggested that the primary fault is in the liver, but there is no post-mortem evidence of any change in that organ beyond the wasting, which the spleen and kidneys equally undergo. It is essentially a tropical disease, and has been most often observed in India, Burmah, Cochinchina and Java. It has gained the name of hill-diarrhœa in India owing to its comparative frequency

among persons who have passed from the great heat of the plains to the vicissitudes of temperature found in the hills. This fact has been held to prove that exposure to cold and damp, or sudden changes of temperature, are determining causes.

The *treatment* at the onset of the disease must be guided by the general condition; it may be necessary to give a saline laxative combined with ipecacuanha if there be hepatic congestion; if much colic and diarrhœa be present, small doses of laudanum or Dover's powder may be given. When the disease is established, the patient should be put on an exclusively milk diet; from 4 to 6 ounces being taken every hour. When the tongue ceases to be glazed, and the stools assume a normal appearance, beef-tea, meat juice, raw eggs and farinaceous food may be added to the diet, but milk alone may have to be continued for as long as six weeks before this stage is reached. In the later stages of recovery quinine and iron will be useful.

DAWSON WILLIAMS.

DIARRHŒA, INFANTILE, is a term which has come into use rather because infants and young children are extremely liable to attacks of diarrhœa than because the morbid changes have any special character. Various types may be distinguished as a matter of clinical convenience, but no hard-and-fast lines can be drawn.

Simple Catarrhal Diarrhœa.—The infant is suddenly taken with griping, quickly followed by watery motions, containing at first some feculent matter and undigested curds. The amount of general disturbance varies, the child is restless, the tongue is generally furred, and there may be distinct pyrexia, which subsides as the flux is established. Vomiting is common, caused by associated gastric catarrh. Such attacks are traceable either to errors in diet, or to exposure to cold, and the first point in treatment is to administer a mild aperient, such as castor oil (ʒi) or rhubarb and soda (āā grs. v, with powdered cinnamon); the belly should be kept warm with a flannel binder or a layer of cotton-wool, and the milk should be freely diluted or withheld altogether, being replaced by weak veal-broth; most cases yield readily to this treatment, but recovery may perhaps be hastened by the administration, for a few days, of an antacid mixture (*e.g.*, sodium carbonate and dill water). If the diarrhœa

continue, rhubarb and opium should be given (tinct. opii ℥ss, spir. ammon. aromat., tinct. rhei, spir. chloroformi āā ℥iij in dill or caraway water), or chalk and catechu. If the stools are frothy, the aromatic chalk powder should be given once or twice a day.

Acute inflammatory diarrhœa is a term which may be conveniently used to embrace the severer forms of simple catarrhal diarrhœa and the very numerous cases of summer diarrhœa which are closely allied to cholera infantum (*q.v.*) both in their ætiology and symptoms. The attack commences with griping, often accompanied by vomiting; the stools at first contain curds and the skins of plums or scraps of other fruit which the child may have been allowed to swallow, but they quickly become watery, offensive, and either brown or green in colour. In less serious cases, however, they may be pale and semi-solid. The general symptoms are severe; the temperature as a rule is raised, and may reach 106° or 107° F. in the rectum; the pulse is hurried and weak, the skin harsh and dry, the face sunken, the lips parched, and the tongue red, small, and rather dry. If, however, gastric catarrh be present, the tongue is furred, and vomiting is a prominent symptom.

The *diagnosis* from enteric fever is often difficult, and not always possible at first; the severity of the early diarrhœa, and later the absence of enlargement of the spleen, assist in the diagnosis, which is confirmed by the early cessation of the symptoms in favourable cases. In protracted cases, the aspect of the child—drowsy, impassive, with rapid irregular pulse, pinched features, inelastic skin, and half-closed eyes—some-what resembles that seen in advanced tubercular meningitis, and to this condition the term “spurious hydrocephalus” has been applied. The depression of the fontanelle, the low or subnormal temperature, and the history of the illness, usually make the diagnosis clear.

Owing to the great exhaustion which is rapidly produced, especially in weakly children, a guarded *prognosis* must be given; unfavourable symptoms are continuance or marked increase of the pyrexia, early collapse, violent vomiting, and very frequent watery stools.

The *pathology* is probably not the same in all cases; in some the catarrh is excited by decomposing food, in others by exposure to cold, and in others again it is traceable to miasmatic influences (*see* CHOLERA INFANTUM). The catarrh is

not uniform; it is most commonly seen in the jejunum, and in the ileum just above the cæcum, where shallow ulcers are often present. Occasionally minute patches of false membrane give the mucous membrane an appearance resembling that which would be produced by sprinkling it with bran.

The disease is most often seen in hand-fed infants, and in these the first step in *treatment* is to entirely exclude milk from the diet, which should be restricted to veal or chicken broth, or whey and barley-water; konmiss in small dose is sometimes useful; the food must be given in small quantities. The belly must be kept warm by a covering of cotton-wool retained by a flannel binder, and the child nursed by a competent person in a well-ventilated room. If the temperature continue high, recourse ought to be had to cool or tepid baths (about 70° F.), administered with caution; when prostration comes on, stimulants must be given, good brandy being the best; warm mustard baths may be employed. At the onset it is advisable to give a dose of castor oil, and this may be followed by ipecacuanha and opium with a carminative (℞ Tinct. opii ℥ss, tinct. zingiberis, vin. ipecac. āā ℥ij, aquam ad ℥ss, every three or four hours). When the stools are green, dilute lactic acid may be added with advantage. In acute summer diarrhœa the perchloride of mercury (gr. $\frac{1}{3}$) frequently repeated is sometimes effective. Astringents are not of much use until the temperature has fallen to about 100° F.; the vegetable astringents are generally to be preferred, and either the extract of hæmatoxylon (grs. ij or iij), the extract of rhatany (grs. ij or iij), or the tincture of catechu (℥iv to ℥viij) may be combined with aromatic chalk and a minute dose of opium; in some cases aromatic sulphuric acid (℥iv) combined at first with opium is very useful.

Chronic inflammatory diarrhœa is often observed as a sequel of an acute attack, but may arise insidiously; the wasted and anæmic condition of the child being the first thing to attract attention. The child will be found to be liable to frequent attacks of diarrhœa, the stools being thin, foul, and of a dark-brown colour; sometimes they contain a peculiar green material like chopped spinach. In the intervals between these attacks three or four pale, copious, offensive, semi-solid stools are passed daily. The belly is distended by flatus, the appetite is capricious, being often voracious,

but the general nutrition fails. To this condition the term "consumption of the bowels" is often applied, but a careful physical examination will usually distinguish it from tubercular disease. The intestines contain patches of chronic catarrh; the mucous membrane is of a dark-grey or dusky-red colour, enlarged follicles project on the surface, and ulceration more or less extensive, but always superficial, commonly exists in the ileum.

The *prognosis* must always be guarded, especially among the children of the poor in large cities.

The most important points in *treatment* are food and clothing; milk, even diluted with lime-water and barley-water, can seldom be digested, and must be replaced by broths, whey, and barley-water, and good malted food made with whey. Children above one year generally do best on a diet mainly consisting of raw meat and thin bread and butter, or raw meat and jelly. Drugs are very uncertain in their action. During an exacerbation, if the stools are brown and offensive, phosphate of soda (grs. v to viij) with laudanum (℥ss) sometimes succeed; in other cases an aromatic mixture containing rhubarb and the above dose of laudanum will be of use. Pepsin (grs. iij) or papaine (Finkler), administered three or four times a day shortly after a meal, is most successful in many cases. In all cases, but especially in those associated with rickets, cod-liver oil in small doses should be cautiously tried, guarded at first by opium, and it is often surprising to note how soon it is well taken.

Lienteric diarrhœa is a form of diarrhœa not often observed in infants, but common in children over two years of age. Each meal is quickly followed by griping pains, which do not cease until a fluid motion, generally containing scraps of undigested food, is passed. It appears to arise from an undue irritability of the peristaltic apparatus, and is associated with chronic gastro-intestinal catarrh. In children it is best treated by attention to the clothing of the abdomen, and the administration of a mixture containing minute doses of arsenic, nux vomica and opium; an alkaline carminative with a minute dose of opium may be given to an infant.

Dysenteric diarrhœa, using this term to signify the symptoms produced by a catarrhal inflammation of the large intestine, is a very common disorder of children in temperate climates; it is sometimes incorrectly spoken of as dysentery.

In its acute form the symptoms are tenesmus and colic followed by severe straining at stool, the motions passed consisting largely of mucus, the faecal matter being often well formed; the lower part of the rectum is often prolapsed with each stool, and it may be difficult or impossible to return it. The general condition of the infant or child quickly deteriorates owing to pain, irritability and pyrexia, and the *prognosis* is grave if the prolapse and tenesmus be not quickly relieved. There is a general catarrh of the mucous membrane of the large intestine, and shallow ulcers, which are at first circular, but later become irregular, are commonly present. In chronic cases the general symptoms are those of ordinary chronic inflammatory catarrh, but the stools contain large quantities of slimy mucus, easily recognized; tenesmus is a prominent symptom, and prolapse of the rectum is common.

In the *treatment* of these cases in the acute stage, in addition to the general remedies above recommended, medication should be directed to the lower bowel. A small starch enema (3ss) containing 3 or 4 minims of tincture of opium may be given twice a day, and a thick starch poultice applied over the prolapsed bowel. In the chronic stage astringent tonics by the mouth, and enemata containing catechu or rhatany injections are useful. Marked excess of mucus in the stools is an indication for small doses of castor oil guarded by opium.

DAWSON WILLIAMS.

DICROTISM.—When a second beat of the pulse can be perceived by the finger, the pulse is said to be dicrotic. This second beat is almost always the great secondary wave which follows immediately upon the closure of the aortic valves, and is generally supposed to be a wave of recoil caused by this closure, and reinforced by an oscillation set up in the aorta. The conditions most favourable for the production of the dicrotic pulse are a left ventricle acting powerfully with a low state of arterial tension. (*Vide* PULSE.)

DIGITALIS, Poisoning by.—All parts of the plant are poisonous. Poisoning is more commonly the result of repeated doses than of a single large dose. The *symptoms* come on very soon, vomiting being the chief; very often there is also purging and pain in the abdomen; thirst, noises in the head, suppression of

urine, clammy sweats and dilated pupils are commonly observed, but the condition of the pulse is the point of chief importance. At first it is increased in frequency, but soon becomes slower, until ultimately the beats are much fewer than normal. Death often occurs suddenly from syncope.

Post-mortem Appearances.—Nothing very definite may be discovered. The right side of the heart may be distended, the left empty; the blood is generally dark and fluid; the stomach may be congested.

Treatment.—Vomiting should be encouraged by emetics, and the stomach-pump should be used. Stimulants and hot tea or coffee, or 20 grains of tannic acid in hot water, may be given frequently. Aconitia gr. $\frac{1}{15}$ has been recommended for hypodermic administration as an antidote. It is essential to keep the patient in a recumbent position until some time after all symptoms have passed off.

DIPHTHERIA.—An acute, infectious and contagious disease, the chief characteristic of which is the development on the mucous membrane of the pharynx, nose and larynx, and on abraded surfaces, of a fibrinous exudation or *false membrane*.

Symptoms.—The onset may be almost sudden, but is more often insidious, the period of incubation usually lasting from two to seven days. The first symptoms are a slight feeling of indisposition, headache, with some fever, stiffness of the neck, and tenderness about the angle of the jaw, pain on swallowing, and a sore throat of a not very acute character. The mucous membrane of the soft palate and tonsils will be found reddened uniformly or in patches; soon a few whitish-grey spots are seen near the base of the uvula or on the tonsils. Gradually the spots coalesce to form patches, the patches run together, and at the same time become thicker. The whole of the soft palate and tonsils may thus be covered with a thick greyish or yellowish white layer, which may envelop the uvula like a finger-tip.

At first the exudation is not very adherent, but as it grows in thickness it becomes more firmly attached, so that when the whole membrane is formed it cannot be removed without some force, and leaves behind a raw and bleeding surface, on which it is speedily reproduced; if left to itself it gradually gets loose and comes away. The membrane is more

closely adherent to the tonsils than to the palate. Sometimes no definite membrane can be seen, the parts being simply swollen, and of a dull greyish colour. The membrane often extends into the cavity of the nose; indeed, it is rare not to have some nasal discharge. Epistaxis is of occasional occurrence, and may in rare cases prove a source of danger or even be the cause of death. The disease may also spread along the Eustachian tube, causing otitis, or along the lachrymal duct, and set up conjunctivitis. The so-called diphtheritic ophthalmia, however, has nothing in common with diphtheria, being simply a chronic membranous inflammation of the conjunctiva. The membrane may either spread to the larynx or the disease may attack that part primarily, a condition to which the name "croup" used to be and is, by some few writers, still applied. It may be surmised that the larynx is affected when hoarseness, stridulous breathing, dyspnoea, aphonia and recession of the chest walls make their appearance. If possible a laryngoscopic examination should be made, but this cannot always be done in the case of young patients, and it is not advisable to persist should the patient struggle much. The younger the patient the more likely is the larynx to be the part primarily attacked; such, indeed, is the rule in infants under two years.

At an early period of the disease the glands in the neck become enlarged, the gland at the bifurcation of the carotid a little behind and below the jaw, being the first affected; the neighbouring glands and peri-glandular tissues subsequently suffer, and a considerable swelling of the whole side of the neck may result; the enlarged glands are more or less tender.

The membrane gradually takes on a brownish tint, and the breath obtains a peculiar sweetish and very unpleasant but characteristic smell. There is not much fever, the temperature in some cases being scarcely raised, but it may reach 102° F. The pulse is generally increased in frequency and the heart's action weakened. In all cases of diphtheria the state of the pulse should be most carefully noted; sometimes it becomes extremely infrequent—a sign of bad omen. The bowels tend to be constipated; vomiting is rarely present, but is an unfavourable sign. Albuminuria will be found in a considerable proportion of the cases; the urine also often contains blood-corpuscles and epithelial casts; general anasarca is, however never ob-

served, except when scarlet fever has preceded the diphtheria.

The duration of fatal cases is generally a week or ten days; recovery in a mild case will often be assured before the end of the first week. Twelve days would be a safe term of quarantine for a person who had been exposed to diphtheria; after an attack he should not be allowed to go amongst the healthy in less than three weeks from apparent convalescence. One attack affords no absolute protection against subsequent infection, although it rarely happens that an individual is twice the subject of the disease. Some persons, however, seem to be more predisposed to it than others. It is safest to regard all forms of acute membranous inflammation as diphtheritic, and to treat them accordingly.

Sequelæ.—Certain phenomena referable to the nervous system are apt to follow an attack of diphtheria. They are loss of voluntary power, distributed over the whole body, most constant perhaps in the palatal muscles, and generally accompanied by anaesthesia of the soft palate; sometimes there is a certain amount of general anaesthesia. There may be loss of the knee jerks, and occasionally of the superficial reflexes. Loss of accommodation is an early symptom, and one almost pathognomonic; strabismus and ophthalmoplegia externa may also occur.

The speech is indistinct and nasal, fluids return through the nose, and the patient cannot drink without coughing and choking. The degree of loss of power may vary from a mere slight debility to absolute helplessness. Sometimes the gait is decidedly ataxic. The pulse, especially in the early stages, is liable to be weak and irregular, and cough is often present. Paralysis of the muscles of the neck and of the intercostals or diaphragm is far from uncommon, and the involvement of the latter is of serious import, as, owing to the inability of the patient to fix his chest, the cough becomes feeble and ineffective. Paralytic sequelæ are rarely seen before the third week from the onset of the diphtheria or after the sixth week in children, but in adults they may appear much later; indeed, in children the whole affection seems to run a sub-acute course, in adults a chronic one.

The gravity of the complication will depend almost solely on the implication of the chest walls; if these are affected, then a very little pulmonary catarrh will render recovery doubtful. The loss of

the knee jerks and the paralysis of accommodation would appear to be the earliest symptoms, but an excessive knee jerk has sometimes preceded its disappearance. In a few cases some of the muscles have presented the reaction of degeneration, and this has persisted after convalescence was well established. In the majority of cases of diphtheritic paralysis recovery takes place, but the prognosis must be guarded, as a considerable number die, and there is reason to think that the paralysis may in a few instances be permanent, but this has not yet been proved. Albuminuria is sometimes found after an attack; presumably it is a relapse from a nephritis which took place during the diphtheria.

Diagnosis.—In a well-marked case this presents little difficulty, but it is not always easy to distinguish between follicular tonsillitis and diphtheria, or to definitely exclude a diphtheritic element in some cases of tonsillitis. If the onset of the disease be sudden, the temperature high (103° – 104° F.), the tonsils much enlarged and the membrane upon them in patches corresponding to the crypts, and if the enlarged cervical glands be tender, the case is probably one of follicular tonsillitis. The absence of membrane or of albuminuria is by no means inconsistent with diphtheria. The diagnosis of the laryngeal cases in the absence of any membrane on the fauces is often exceedingly difficult; even a sudden onset of symptoms in the middle of the night is not conclusive against diphtheria.

Prognosis.—The danger will, as a rule, be directly proportional to the youth of the patient. The extension of the membrane down the trachea and into the medium-sized bronchi, an event which may occur even after the performance of tracheotomy, is perhaps the complication most to be feared. Sloughing of the wound after tracheotomy is also not uncommonly a cause of death in diphtheria. Occasionally mediastinal emphysema occurs from the rupture of alveoli, or the air enters the thorax along the deep cervical fascia after tracheotomy. Cases in which the nose is much involved also frequently terminate fatally. The condition of the heart is of great importance in forming a prognosis. As has been already stated, vomiting is of very bad augury, as also is the presence of a large quantity of albumen in the urine. Every complication adds to the danger, and even when the patient is safely through the diphtheria there are the great risks of subsequent paralysis to be encountered.

However mild the case may apparently be, the prognosis, therefore, should be a guarded one.

Morbid Anatomy and Pathology.—In a recent case of diphtheria on post-mortem examination, membrane may be found on both aspects of the soft palate and uvula, and in the larynx, but it is rarely directly continuous from one spot to the other. The membrane may be found in the trachea and the bronchi; not, however, often beyond the second division of the tubes, but a thick muco-purulent secretion can be traced into the finer tubes. The lining membrane of the larynx, trachea and bronchi will be found reddened beneath the membrane. The membrane is never so adherent in the air passages as in the fauces, probably owing to differences in the character of the two surfaces.

Membrane is occasionally found in the cesophagus, and still more rarely in the stomach. Micro-organisms may be found in and beneath the membrane, and even penetrating the apparently healthy tissues, but no special form peculiar to diphtheria has as yet been recognized. The heart, especially in those cases which have proved fatal through syncope, may show granular degeneration somewhat analogous to that met with in enteric fever, and sometimes minute thrombi will be found amongst the columnæ carneæ; in a few instances there has been endocarditis apparently of recent date. The kidneys in those cases in which albuminuria was present show the changes of sub-acute parenchymatous nephritis. Certain changes have been found in the grey matter of the spinal cord and in the peripheral nerves, but the exact pathology of diphtheritic paralysis is still doubtful; the lesion must of necessity be slight, since recovery is usually so complete; the fatal result is determined, not by the character, but by the situation of the lesion. The mildest attacks, of which little or no notice has been taken, are perhaps the most apt to be followed by paralysis.

Etiology.—It has been contended that diphtheria is primarily a local disease, but this is hardly compatible with the fact that in many cases the general symptoms are quite out of proportion to the local; and it is now looked upon as a specific disease, with a special tendency to affect the throat. The disease is certainly communicable, and probably depends upon the presence of a micro-organism, but the exact nature of the latter is still uncertain. Diphtheria

has appeared in some cases to be due to polluted water, bad drainage, or foul air, and it is certain that it may be transmitted by milk. Cases are especially common amongst those living in mews or in the immediate vicinity of stables, and there are reasons for thinking that it is sometimes transmitted from animals to human beings.

Treatment.—The membrane should not be forcibly removed. Ice is an excellent local application, and the patient should be encouraged to suck ice. Drugs may be applied locally in the form of powders or spray; iodoform and carbolic acid may thus be applied to the fauces every four hours with great advantage, or solutions of carbolic acid (grs. iijss-5j), tannic acid, or perchloride of iron may be applied with a brush. Good results have followed the use of the liq. hydrarg. perchlor. as a spray and throat wash. The spray and powders have the advantage that in laryngeal cases the remedy, being to a certain extent inhaled, also reaches the larynx. When there is much swelling of the neck, nothing does so much good as ice compresses; they should be changed every two hours.

Internally, quinine, strychnine, perchloride of iron, and chlorate of potash are the remedies most in favour; the dose should be small, and the medicine given every three or four hours. The internal use of calomel in doses of from 2 to 5 grains, every two or three hours until free catharsis is produced, has many advocates and has certainly given good results in the hands of some practitioners. It is all-important but a matter of considerable difficulty to get the patient to take a sufficiency of nourishment. When there are any signs of cardiac failure, stimulants must be given freely.

Tracheotomy will often be necessary; the indications for the operation are inspiratory recession of the intercostal spaces and increasing dyspnoea. Intubation of the larynx has been practised, but rarely with as satisfactory results. The patient should be kept in bed and given a liberal supply of nourishment for at least a week or ten days after the membrane has disappeared in order to diminish the risk of paralysis, which undoubtedly is far more liable to follow a neglected diphtheria than when the patient has been carefully nursed. In the treatment of diphtheritic paralysis absolute rest in bed and protection from draughts are of the first importance; a liberal diet is equally necessary. If the palate be

much involved, the patient should be fed through the mouth or nose by means of a tube. Belladonna is the only drug that has seemed to exert any definite influence, and a trial should certainly be given to it in all serious cases.

JOHN ABERCROMBIE.

DIPLOPIA, or double vision, is a condition which necessarily results when the axes of the eyes are not parallel. It is often due to some error of refraction, and always accompanies paralysis of one of the extrinsic muscles of the eyeball, and is often an important symptom in disease of the brain or spinal cord. Diplopia may exist without there being any recognizable degree of squint. Defects in the lens may give rise to double vision with one eye alone; it is uncertain whether a lesion of the higher centres in the brain on one side only can produce double vision with one eye.

DISINFECTION (including Disinfectants; Germicides; Antiseptics; Deodorants).—The destruction of the contagium of infection.

The views held as to the nature of the infection which is to be destroyed must necessarily influence the selection of the method.

It is admitted that the virus of many infectious disorders is due to the action of a living *materies morbi*, in the form of microscopic germs—"microbes"—which live and multiply within the tissues of the patient. But this has, as yet, been proved to be the case in only a comparatively small number of diseases. In the present state of our knowledge, therefore, we must allow that there may be infectious maladies the contagium of which is not microbic, although capable of being destroyed if attacked in the proper way. Upon either view, disinfection needs to be thorough; for, if partial and incomplete, it is worse than useless, deluding with a false sense of security.

In this connection it should be remembered that a true *disinfectant* is an agent which destroys the contagium of infection; a *germicide* is a substance which, when added, in not less than a certain proportion, to a culture of the particular microbe under observation, kills both it and its spores outright; the term is not synonymous with disinfectant, since there may be infectious poisons not due to the action of "germs."

Antiseptics are agents which arrest decomposition (*sepsis*); but (1) this arrest may occur only so long as the decom-

posable material is submitted to the inhibiting action of the antiseptic; or (2) the antiseptic employed may suffice to destroy the fully developed septic microbes without destroying the vitality of their spores.

Deodorants are more or less fragrant substances which certainly mask the evil odours that commonly attend septic processes; but this substitution of a pleasant smell for a disagreeable one is no guarantee that the actual poison which the bad smell served to indicate is destroyed.

In the order of their hygienic value, then, these substances would rank thus:—(1) Deodorant—uncertain, dangerous, and delusive; (2) Antiseptic—locally useful so long as the action is maintained; (3) Germicide—valuable, and safe when the virus is microbic; (4) Disinfectant—certain and safe under all circumstances when used in the proper way.

Disinfectants can be classified in accordance with their mode of action, as—A. Oxidizing agents, including (1) those which oxidize directly, *e.g.*, ozone, potassic permanganate, &c., and (2) those which oxidize indirectly by the abstraction of hydrogen, *e.g.*, chlorine, chloride of lime, &c.; B. De-oxidizing agents, *e.g.*, carbolic acid, sulphurous acid gas, &c.; and C. Substances which destroy the pathogenic virus by some other form of physical action, *e.g.*, corrosive sublimate, heat, &c.

It is obvious that the members of groups A and B must not be used together, since their modes of action are chemically antagonistic; thus, carbolic acid may be employed in conjunction with the fumes of burning sulphur, but neither should be used with Condyl's fluid, chlorine gas or sanitas.

The contagia of the various forms of infection vary greatly as regards their virulence and their power of resistance to destructive agencies; the spores of *bacillus anthracis* and the virus of scarlatina are tenacious of vitality, whilst the infection of measles is short-lived and can be destroyed by free exposure to fresh air and bright sunshine.

As soon as an illness is proved, or even suspected, to be infectious, the patient should be isolated, preferably in a separate building, or, if this be impossible, in a room at the top of the house. Outside the door of this room a sheet moistened with some volatile disinfectant should be hung (*vide infra*). No persons should enter the room save the nurse and the doctor, and any articles which must

be removed during the illness (*e.g.*, crockery and soiled linen) should be previously immersed in a disinfecting solution. The sick-room should be light and airy and should have an open fireplace. All superfluous furniture, together with curtains, carpet and hangings, should be removed, and the room should be cleaned, aired and warmed before it is occupied by the patient. The water-supply and the rain-water pipes should be looked to; drains, cisterns and sinks must be examined, tested and kept continuously disinfected. The sick-room should be kept well ventilated.

But the treatment of a case of infectious illness is incomplete unless adequate measures be taken for the efficient disinfection of the patient and of his excreta; of the clothing, bedding and furniture with which he has been in contact; and of the sick-room itself. The following list includes all those measures which are practical and serviceable to this end.

For the disinfection of—

THE PERSON.—*The mouth* may be rinsed with a weak solution of Condyl's fluid (5j to Oj), to which a little eau de Cologne may be added; or with a solution of peroxide of hydrogen, or boroglyceride (1 in 100). *The skin* in scarlatina may be daily anointed with carbolic oil (1 in 60), or with 1 part of sanitas oil to 20 of olive oil; in the later stages of desquamation a lanoline ointment containing 1 per cent. of carbolic acid is useful; it may be sponged with a tepid solution of sanitas or of Condyl's fluid, or washed with carbolic soap (10 per cent.), sanitas soap, or lanolin-carbolic soap. When a disinfecting bath is given, care should be taken to thoroughly cleanse the nails, scalp, hair and all the orifices of the body; after such a bath the patient should put on fresh, clean (disinfected) clothing. In diphtheria all wounds and abraded surfaces should be protected by smearing them with carbolized vaseline (1 in 40), if they cannot be sealed with styptic collodion.

What may be termed prophylactic disinfection consists in the treatment of persons who have been exposed to infection with drugs which are supposed to destroy the infective virus as it enters the body, or to prevent its development; thus good results are claimed for the administration of small doses of arsenic and of the biniodide of mercury with potassic iodide, during the prevalence of scarlet fever epidemics. *Cabs*, which have been used for the conveyance of infectious

cases may be disinfected with chlorine or with sulphurous acid gas (*vide infra*).

THE EXCRETA. — *Feces, urine and sputa* should be received into vessels containing a teacupful of a solution of carbolic acid (3iv to Oj of warm water), chloride of lime (1 lb. to Oj), Condy's fluid (3j to Oj), sulphate of iron (green copperas) (1 lb. to Oj), chloralum or sanitas. Similar solutions should be used for flushing and disinfecting drains, sinks, water-closets, and for rinsing dirty utensils and crockery before washing them in hot water.

CLOTHING, FURNITURE. — Every infected article which is useless or can be spared should be burnt. Carpets, curtains, bedding, other than linen, including blankets, mattresses, bolsters, pillows and woollen clothing, should be exposed in a proper apparatus to heat. If dry air be employed, the exposure should be such that the centre of the bulkiest articles is maintained at a temperature of not less than 220° F. for at least one hour. In disinfection by steam, a temperature of 212° F. for five minutes suffices (Dr. Parsons). It would be useful to enclose a fragment of a fusible alloy which melts at the minimum temperature desired in a glass tube, and to place this in the centre of the bulkiest article requiring disinfection (*e.g.*, a mattress). This could be withdrawn and examined when the process was completed, and the fusion of the alloy into a button would prove that the mattress had been exposed throughout its mass to the required temperature. Linen and cotton articles should be quickly rinsed in a solution of chloride of lime (3j to Oj) or of Condy's fluid (3jss to Oj), then at once wrung out in clean water, and *boiled* at the wash. During the illness, clean soft rags should as far as possible be used instead of pocket-handkerchiefs and napkins, and burned directly they are soiled. Furniture and floors should be washed with a tepid solution of carbolic acid, Condy's fluid, or chloride of lime, and then scrubbed with hot carbolic soap and water.

THE SICK-ROOM. — During the illness, the sheet suspended outside the door must be kept moist with solutions of carbolic acid or sanitas. The room may be sprayed with sanitas solution, or with diluted Condy's fluid, several times a day. After the convalescent has left the room, and when the bedding and other infected articles have been removed, the room is to be disinfected by the use of chlorine or by the fumes of burning sulphur.

When chlorine is to be used, all windows, doors, and other openings having been closed—as directed below—and metal surfaces having been smeared with oil or vaseline, half a pint of hydrochloric acid is poured on to a quarter of a pound of manganese dioxide placed in a large dish elevated on a table in the centre of the room. The room must remain closed for six hours before fresh air is re-admitted and the walls and furniture washed. Chlorine bleaches, and this method is less convenient than the employment of sulphurous acid gas. In order to make efficient use of this latter agent, windows, ventilators, and fire-places must be tightly closed, slips of paper pasted over cracks and a sack of chaff or shavings stuffed up the chimney. It is important to see that enough sulphur is used; the proportion recommended by Parkes is 1 lb. of sulphur to each 1000 cubic feet of space; the sulphur should be divided into two portions or more if the room be a very large or long one. The roll sulphur, previously broken into small lumps, is put into an iron or tin dish large enough to hold it all when melted; this dish is placed on a brick or otherwise supported in an iron pail or stout earthenware pan, and some water or sand is placed in the bottom of this pan to receive any molten sulphur that may run over. The sulphur is most easily lighted by igniting spirit of wine previously poured over it. The door is then closed for from eight to twelve hours. At the end of this time the room may be cautiously entered, the windows opened, the fire lighted and the walls and furniture washed with the dilute carbolic acid solution, or with hot water and carbolic soap.

If their disinfection cannot be otherwise ensured, articles of clothing and linen may be suspended on lines stretched across the room before the sulphur is ignited, but the sulphur fumes bleach vegetable dyes and, by forming sulphuric acid with the oxygen and moisture of the air, are apt to rot the fibre of substances exposed to their action for any length of time. The various disinfecting "cones" supplied by the Chemical Carbon Company afford a ready but slightly more expensive means of practising the same method of aerial disinfection.

Should a case of infectious disease terminate fatally, the body should be washed with strong carbolic solution (1 in 20), and may also be sprinkled with MacDougall's or with carbolic powder; it

Disease.	Isolation of the Patient until—	Quarantine, after Exposure to Infection, for—
Chicken-pox .	Every scab has fallen off . . .	Eighteen clear days.
Cholera . . .	Convalescent	One week.
Diphtheria .	Convalescence is completed (in any case for not less than three weeks), there being no longer any sore throat or discharge from throat, nose, eyes, or ears, and no albuminuria.	Not less than ten days, if the throat be <i>quite</i> natural in appearance at the end of this time.
Enteric fever (Typhoid)	Appyrexia is established and all secretions are natural.	Not less than ten days.
Measles . . .	Not less than three weeks have elapsed from the appearance of the rash, and all cough and desquamation have ceased.	Sixteen days.
Mumps . . .	Not less than four weeks have elapsed, and all glandular swellings have subsided.	Twenty-four days.
Relapsing fever	Convalescence is completed . . .	Twenty-four days.
Ringworm of body	Cure is complete	Until careful and thorough examination has proved the absence of infection.
Ringworm of scalp	Careful examination of the whole scalp shows a complete absence of diseased hairs and stumps.	Until careful examination has shown complete absence of all signs of the presence of the fungus, followed by thorough application of an efficient "preventive" ointment or lotion.
Rötheln (German measles)	The end of second or third week, according to the severity of the attack.	Sixteen days.
Scarlatina .	The end of sixth week from the appearance of the rash, provided there be no longer any desquamation, albuminuria or congestion of the fauces.	Fourteen days.
Small-pox . .	Every scab has fallen off . . .	Eighteen days.
Typhus . . .	Convalescence is completed . . .	Fourteen days.
Whooping-cough	The end of the sixth week, if the peculiar paroxysmal cough and the whooping have ceased, or for a shorter period, if <i>all</i> cough have completely ceased.	Twenty-one days at least.
Yellow fever .	Convalescent	Not less than fifteen days.

N.B.—Complete disinfection of person and of clothing must be carried out at the termination of the period of isolation or of quarantine.

should be buried with as little delay as possible.

It is a good rule in practice to regard every disinfectant as being poisonous. Medical men should be careful to avoid carrying infection. Visits to infectious cases should be made not oftener and not of longer duration than is really necessary, and not when exhausted by fasting or fatigue. The hands, &c., should be thoroughly cleansed in a disinfectant and with soap and water when the visit is over, and every possible advantage should be taken of the disinfecting properties of fresh air. It is a good plan on entering the patient's house to put on, over the ordinary clothing, a large mackintosh, kept there for the purpose; this can be sponged over with a disinfectant on leaving the sick-room.

ISOLATION and QUARANTINE are terms often employed indiscriminately and at random, but they can be usefully distinguished. Thus, isolation implies the continued separation of the infectious patient from the healthy until after he has ceased to be infectious; while quarantine (no longer used with its original signification of a forty days' detention) means the segregation of *possibly* infected persons until after the period has elapsed at which they would (if infected) develop characteristic signs of the disease. The duration of this period will necessarily depend upon that of the incubation period of the particular disease to which they have been exposed; it should, indeed, be a day or two longer; and, on its termination, thorough disinfection of the person and of all fomites, such as the clothing, should be carried out before such persons are again permitted to consort with the healthy.

If this disinfection be omitted, the mere quarantine affords practically no safeguard against the transmission and spread of infection, owing to the persistent vitality of the virus, which is especially notable in certain diseases—*e.g.*, scarlet fever. Hence, persons who have recently been in contact with a patient suffering from an infectious disease, or who have been exposed to the same source of infection, should be at once separated from others and kept under observation "in quarantine," for at least a space of time corresponding to the full incubation period of the disease in question; if in good health at the end of this period, they may resume their usual relations to society, after thorough disinfection of their persons and clothing.

The table given on p. 187 indicates the periods of isolation and of quarantine which are generally applicable in the case of the principal infectious diseases.

C. E. SHELLEY.

DISSEMINATED SCLEROSIS (*Multiple Sclerosis; Insular Sclerosis*).—A disease characterized by the formation of patches of sclerosis in many parts of the cerebro-spinal system.

The disease has been described as occurring in three forms—namely, cerebral, spinal and cerebro-spinal, according to the parts most affected; but for all practical purposes it will be sufficient to describe the cerebro-spinal variety, which is the one most commonly met with.

Symptoms.—The onset is gradual. Generally the first symptom to appear is weakness of both legs, the arms being after a time similarly affected. There is no affection of sensation, or of the sphincters. After some months attacks of transient diplopia occur, followed by amblyopia and subsequently by nystagmus. *Amblyopia* remains as a permanent symptom, but it very rarely ends in complete blindness. The optic discs are as a rule unaffected, but in some cases atrophy follows. In a typical case the chief symptoms are the peculiar speech, nystagmus, tremors on voluntary movement, general weakness of the limbs, with some rigidity of the legs and increase of the tendon reflexes.

The *speech* is very characteristic: it is slow, and each syllable is pronounced with difficulty and after a slight pause, giving it what is termed a "scanning" character. In some cases this is so marked that each syllable is blurred out with much effort in an explosive manner, so that the speech becomes unintelligible. Occasionally this condition is associated with tremors of the lips.

The *tremors* occur *only* on voluntary movement. When lying down the patient is quite quiet, but, on being told to touch his nose with the fore-finger, the arm begins to tremble and this increases as the finger approaches the point to be touched, but the movement is *not* increased by closing the eyes. Making the patient raise a tumbler of water to the lips is a common test for this condition. In walking, the leg is brought forward tremulously, sometimes causing the whole body to shake, then the foot which is on the ground trembles whilst the other is brought forward, but there is no throwing about of the legs or stamping with

the heels as in locomotor ataxia. Shaking of the head, when it is raised off the pillow, occurs in some cases, and tremor of the tongue when it is protruded.

Nystagmus of the eyes is a very constant symptom; it is conjugate, and becomes obvious when the patient looks laterally or up or down. The quick oscillating movements of both eyes which constitute this symptom occur in the direction towards which the patient is looking. In extreme cases nystagmus occurs if the patient be merely told to fix his eyes on an object in front of him, but in the early stages of the disease it is not observed when the eyes are at rest.

Besides the above-mentioned symptoms, three-fourths of the patients suffer from *vertigo* (Charcot), which may be either subjective or objective in character.

Mental changes are present in many cases, and sufferers from the disease are very emotional and, in the advanced stage, attacks of dementia are not uncommon. The expression of the face is described as being stolid, vague and uncertain (Charcot), but this is not sufficiently marked in recent cases to be characteristic.

In the limbs, especially the legs, there is progressive weakness, but no paralysis of any particular movement; the legs tend to become rigid.

The *knee jerks* (patellar tendon reflex) are increased, and *ankle clonus* is usually present.

Sensibility is usually not affected at all, and the sphincters not until late in the disease.

As unusual and late symptoms, Charcot mentions atrophy of groups of muscles of the limbs, bulbar paralysis, apoplectic form seizures, associated with acceleration of the pulse and a rapid rise of temperature.

Three stages of the disease are described:—

(1) From the commencement till the patient has to take to his bed.

(2) When he is confined to bed, but the organic functions are intact.

(3) When the organic functions are affected.

In the last stage the sphincters become involved, diarrhoea sets in, followed by general emaciation, the formation of bed-sores, dementia and death.

The *diagnosis* has to be made from paralysis agitans, in which disease the tremors occur while the patient is at rest and diminish on voluntary movement. In general paralysis of the insane the tremors are usually finer and nys-

tagmus is absent, but the diagnosis from general paralysis is sometimes impossible, as the two diseases may be combined. In *tabes dorsalis* the inco-ordination is increased by closing the eyes. Chorea could hardly be mistaken for this disease, as the movements in the former occur irrespective of voluntary movement.

The *prognosis* is very grave; the disease lasts many years, the age of forty appearing to be the limit of life in disseminated sclerosis.

Morbid Anatomy.—The lesions appear as greyish or semi-gelatinous yellow patches, varying in size from a pin's head to that of a pea or they may even be still larger. They are found in the cerebrum, especially the internal parts, in the pons Varolii, cerebellum, medulla and in the spinal cord, where they occur in both the white and the grey matter.

On *microscopic examination*, the patches are found to consist of an overgrowth of the fibrous tissue (neuroglia) of the part. At the periphery of a patch in the white substance the nerve tubules are seen to be separated by the hyperplasia of the neuroglia. In the zone internal to this peripheral part the connective tissue is more abundant and the nerve tubules have lost their medullated sheaths, retaining only the axis cylinders, which are often much enlarged. In the centre very few axis cylinders remain and the nerve tubules are supplanted by thick bundles of connective-tissue fibrils, nucleated cells, fat globules (the remains of the medullated nerve sheaths), and a few granulation corpuscles. The walls of the vessels are much thickened, especially the external coat. In the patches in the grey matter the nerve cells first undergo yellow degeneration, and subsequently atrophy. If a large patch occur in the lateral or posterior columns of the spinal cord, secondary descending or ascending sclerosis, respectively, ensues and is marked by the occurrence of the symptoms characteristic of these degenerations.

Ætiology.—The disease distinctly pertains to youth and early adult life, the most common age being between twenty-five and thirty years. It may begin as early as fifteen and is rare after thirty. In this respect it differs much from paralysis agitans, which is rare before the age of forty. Females are much more often attacked than males, the proportion being 25 to 9 (Charcot). Exposure to wet and cold and excessive mental grief and anxiety seem to be the most potent factors in the ætiology of the

disease, but in many cases no adequate cause can be discovered.

Treatment has hitherto failed to arrest the disease. Strychnine and nitrate of silver have seemed in some cases to diminish the tremors, but for a time only. The strength of the patient should be maintained by good food and the administration of tonics. A trial may be given to the hypophosphites. No marked benefit has resulted from the use of phosphorus, arsenic or belladonna.

C. E. BEEVOR.

DIURETICS are remedies which cause an increased secretion of urine. They effect this by their influence upon the vascular system or by a more direct action upon the kidneys.

The former class comprises those which raise the blood pressure generally throughout the body, such as digitalis, squill, draughts of water, alcohol, scoparium and the application of cold to the surface, and those which produce dilatation of the renal vessels. Squill and digitalis act in this way also; others are spirits of nitrous ether, belladonna, cantharides and aconite.

Substances which have a more direct action upon the kidney cause diuresis either by the effect of an alteration in the composition of the blood on the renal epithelium, or by an influence upon the vessels. Salines act in both of these ways, whilst juniper, copaiba, turpentine, cantharides and all the aromatic and volatile oils and resins act partly on the renal epithelium. In dropsy dependent upon cardiac failure digitalis and squill are most useful, the other diuretics being more efficient in renal dropsy and in ascites from obstruction to the portal circulation. The action of diuretics is often much increased by the previous administration of a purgative and by the combination of several in one prescription.

DROWNING.--In the event of a dead body being found in the water, the following questions may arise:—(1) Was the deceased alive at the time of entering the water? (2) If so, was death due to drowning? (3) If death occurred before submersion, to what was it due?

The most important *signs* of death from drowning are—the condition of the skin known as “cutis anserina” or “goose skin;” froth at the mouth and nose; the presence of excoriations or abrasions of the skin; retraction of the penis; the presence, in the stomach and

lungs, of water similar in character to that in which the body was found; the presence in the hands or under the nails of mud, gravel, sand, or weeds, taken up from the bottom in the death struggle. The other internal appearances may be those of asphyxia (engorgement of the right cavities of the heart, &c.) or of death from syncope.

When a body has remained but a short time in the water the skin will be pale and present the condition of “cutis anserina,” above referred to, produced by contraction of the muscles acting on the hair follicles. If the period of immersion be longer, a few days or so, the skin becomes white, swollen and sodden, and gradually separates.

A person may fall into the water whilst suffering from syncope, epilepsy or concussion, in which case some of the characteristic signs of death from drowning and of asphyxia will be absent.

In the case of a body being thrown into the water after death, in addition to the absence of the signs of death from drowning, some injury or other sufficient cause of death would be disclosed by the post-mortem examination.

It may be stated that, as a rule, it is extremely improbable that a person could survive entire submersion for two minutes.

In attempting to restore animation in a case of apparent death from drowning, the first thing to do is to clear the mouth and nostrils of any mucus or foreign body. The body should then be placed face downwards for about half a minute to permit any water to run freely out of the mouth. Artificial respiration by Silvester's method should then be performed, as follows:—The patient is placed on his back, the person who is to perform the artificial respiration then grasps the arms near the elbows and slowly brings them up over the head, keeping them fully extended for about three seconds. He then brings them down to the side and compresses the thorax laterally at the same time. This is repeated about fourteen times a minute. It is extremely important that none of these movements should be at all hurried, in order that air may be gradually and regularly introduced into the thorax and squeezed out again, after the manner of normal respiration. The body must as soon as possible be wiped dry and covered with dry clothes, and warmth applied to the extremities. Friction may be used to the extremities, and hot sponges applied over the heart at the same time.

When spontaneous breathing has been established satisfactorily, hot drinks should be given and the patient put to bed and kept warm.

JOHN ABERCROMBIE.

DRY MOUTH (Xerostomia).—This condition, of which few examples have as yet been recorded, was first prominently brought before the profession by Mr. Hutchinson at a meeting of the Neurological Society in 1887, when a patient was shown. Next year this case was published in the *Clinical Society's Transactions*, and in the same volume an example which came under the writer's notice is also recorded. There is little doubt that the condition is a definite clinical state, and hence it was suggested by Mr. Hutchinson and the writer independently that the term "Xerostomia" (*ξηρός*, dry; *στόμα*, mouth) would be an appropriate synonym.

Symptoms.—In all the cases the condition of the mouth has been the same. The tongue is red, devoid of epithelium, cracked and absolutely dry; its appearance is like that of raw beef. The inside of the cheeks, the hard and soft palate are also dry, and the mucous membrane smooth, shiny and pale. The salivary glands appear normal, and no obstruction can be detected in their ducts. The general health remains unimpaired, and it is interesting to observe that in no case has digestive disturbance been described. The urine is normal, and the absence of sugar has been expressly noted. From the absence of saliva speech is often difficult and swallowing has to be assisted by constant sipping. In exceptional cases, dryness of the pharynx, diminished secretion from the nose, arrest of the lachrymal secretion, dryness of the skin and falling out of the teeth have been noted. The disease reaches its greatest intensity rapidly, sometimes suddenly, and then remains without change for years. This condition of dry mouth is clearly not dependent on gross change in the salivary glands, but should probably be ascribed to some persistent functional disorder of the nerve apparatus. The fact that the secretion of all the salivary glands, as well as the buccal glands, becomes arrested strongly suggests the existence of a general controlling nervous centre.

All the subjects hitherto have been women, and most of them were between the ages of fifty and sixty-five; in one instance, however, the onset occurred at the age of twenty-three. In three re-

corded instances the disease began suddenly, being preceded in two by severe mental shock.

Treatment.—The writer has found much benefit follow the use of the tincture of jaborandi in doses of 30 or 40 minims three times daily. Pilocarpin also is useful, but less so than jaborandi. Iodide of potassium has been recommended; mercury, quinine, steel and opium have been tried ineffectually. The application of glycerin to the mouth is of decided value in relieving the local discomfort.

W. B. HADDEN.

DUODENUM, ULCER OF THE.

—**Acute duodenal ulcer** is an occasional sequela of extensive burns or scalds of the surface of the body, but the statements of authors vary greatly as to the relative frequency of its occurrence. Probably a large number of cases recover or give rise to no symptoms. If symptoms show themselves during life, they generally do so between the seventh and twenty-first days, and the condition may prove fatal, especially by perforation, up to the sixtieth day. Acute ulcer has also been observed as the result of exposure to extreme cold.

Chronic duodenal ulcer is a more common condition, and one about which little information is usually provided in text-books. It may result from chronic duodenitis, from the presence of ascariides, and possibly from syphilis, while it is occasionally associated with pulmonary tuberculosis. It may occur, like the majority of gastric ulcers, in connection with anæmia in young women, but far more frequently it is found in older persons of the male sex and of alcoholic habits. Its usual seat is the first part of the duodenum, where the acid gastric juice comes in contact with the wall of the viscus, the nutrition of a part of which is presumably defective. Below the opening of the biliary and pancreatic ducts, where the acid is neutralized, ulcer is of extremely rare occurrence. The ulcer may be situated on the anterior or posterior wall, the symptoms varying accordingly. The pathological appearances, and the theories evoked to account for their development, are the same as those of gastric ulcer, to which reference may be made.

The *symptoms* are generally very obscure, often entirely absent, and when present sometimes indistinguishable from those of gastric ulcer. Pain is, however, generally less acute, the food not being submitted to the same churning move-

ment as in the stomach; it follows the ingestion of food at a longer interval, often two or three hours after meals, and, if evoked on pressure, is so more to the right of the middle line. Sometimes an indistinct sense of resistance or thickening may be detected on palpation. The presence of altered blood in the motions in considerable quantities in connection with such symptoms, and without true gastric symptoms, is often suggestive. If situated on the anterior wall, perforation and rapidly fatal peritonitis often ensue. In the majority of cases, however, cicatrization occurs, with contraction; the pylorus is often thus involved, and may even finally be obliterated, the duodenal symptoms being merged in those of dilatation of the stomach (*g.v.*), or the stomach and the part of the duodenum in front of the contraction may be thrown into one, the pylorus being widely dilated. Adhesions may form with the liver, gall-bladder, pancreas or other surrounding organs, into which the erosive process may extend deeply, while fatal hæmorrhage may occur from the pancreatico-duodenal or hepatic arteries, from the portal vein or even from the abdominal aorta. Thrombosis of the portal vein has also been observed. Periduodenal and peri-hepatic abscesses often form, and may rupture either into the peritoneum or through the diaphragm into the pleura. Obliteration of the choledic duct results in persistent jaundice, the distension of the bile ducts throughout the liver, and multiple hepatic abscesses.

The *treatment* must be on the same lines as for gastric ulcer. Possibly a certain number of cases giving rise to obvious gastric dilatation, if seen before the patient is too exhausted, would be favourable subjects for Loreta's operation of digital distension of the pylorus, or for gastro-duodenostomy—an operation which consists in uniting an opening in the stomach to one in the third part of the duodenum. J. J. PRINGLE.

DYSENTERY is an acute specific disease of the large intestine characterized by inflammation and necrosis of the mucous membrane, by tormina and tenesmus, and by the passage of scanty, non-feculent mucous or blood-stained stools.

The disease is endemic in most tropical and sub-tropical countries; sporadic cases are also rarely observed in temperate climates, and hence the specific nature of the disease has been questioned.

First Stage.—The earliest symptoms of

an attack of acute dysentery are loss of appetite, furred tongue, constipation alternating with diarrhœa, malaise, evening pyrexia and chills.

Second Stage.—The pyrexial symptoms grow more marked after three or four days, though the temperature is never much raised (100° F.); colic becomes troublesome, and the lower bowel, unless diarrhœa have been considerable during the premonitory stage, is emptied of its feculent contents. As the disease develops, colic becomes more painful and recurs more frequently; there is constantly recurring desire to go to stool, and the patient suffers severely from burning pain in the rectum.

Third Stage.—The attacks of abdominal pain and the rectal pain and burning become more frequent and severe, and the calls to defecation do not cease; in the intervals between the attacks of colic, localized tenderness, but no tumour, can be made out; the pulse, which has been gradually increasing in frequency, is now very rapid and weak; there is much depression and exhaustion, and the patient not infrequently faints at stool. Thirst is constant and distressing. The urine is small in quantity, loaded with lithates, and passed with pain and difficulty, or there is retention. The straining at stool is only effectual in passing small quantities of blood-stained mucoid or gelatinous material of a non-feculent character, but having a peculiar odour.

Fourth Stage.—All the above symptoms are aggravated, and a rigid contraction of the abdominal muscles is a notable symptom; the stools are now more copious, contain larger masses of blood-stained mucoid material, and have the peculiar offensive sickly smell very pronounced; they sometimes contain pus, or the mucoid material has a peculiar appearance resembling boiled sago.

Fifth Stage.—The symptoms of nervous prostration become greater, the heart's action and the pulse feebler; the features are pinched; the whole body shrunken, and often covered with a cold sweat; the tongue is brown and dry; portions of sloughing tissue may be found in the stools, which are horribly offensive; hæmorrhage is generally present and may be considerable, greatly increasing the general prostration; abdominal tenderness and rigidity of the abdominal muscles are very marked, and a soft doughy tumour may be felt in the course of the colon. The patient sinks into a drowsy, dull state, and dies from asthe-

nia; or the fatal issue may be hastened by perforation of the intestine, and consequent peritonitis.

Sixth Stage.—The sloughing may be very extensive, so that the sloughs become gangrenous, very large areas or almost the whole of the mucous and sub-mucous tissues being detached; the general prostration is intense, but the colic and tenesmus, which had previously been severe, cease: the abdomen becomes tympanitic, but not tender; everything taken by the mouth is rejected, the features are pinched, the tongue brown and cracked; the prostration deepens into collapse like that of cholera, or low delirium ensues, and the patient dies after a few days. The stools at first contain mucus, detritus and blood-stained gelatinous material, but later are watery, black (the so-called "meat washings"), and have a very offensive gangrenous odour.

The symptoms have been for convenience described in six stages, but no case runs through them all; the first two stages are generally to be distinguished, but vary much in duration; the third and fourth may be hurried through, the patient passing into the fifth or sixth in two or three days; the fifth stage may be well established at the beginning of the second week, the sixth at the end of the first week.

The *diagnosis* from ordinary diarrhœa rests chiefly on the gravity of the general symptoms, but especially upon the acute suffering caused by the frequent attacks of colic, and by the extreme rectal burning and straining; in a later stage the character of the stools gives assistance.

Prognosis.—The absence of complications (of the liver especially), a good pulse, moderate tormina and tenesmus, a pallid expression, absence of extreme offensiveness of the stools, and the early reappearance of feculence are favourable signs. The unfavourable symptoms are persistent fever, quick or feeble pulse, dry brown tongue, severe tormina and tenesmus, sudden cessation of severe tormina, increase of putrescence of the stools, the appearance of gangrenous material and the onset of complications. The previous state of health of the patient and the stage of the disease at which he comes under treatment are important points greatly affecting the prognosis favourably or otherwise. Abscess of the liver is frequently observed after dysentery, and enlargement of the liver and of the spleen, malarial fever and scurvy are common complications.

The *pathology* of dysentery has been much discussed. The essential lesion appears to be an acute inflammation of the whole glandular structure of the mucous membrane of the large intestine; the condition in any given case will vary with the stage and intensity of the inflammation. The first changes are those common to catarrhal inflammation in any situation, and there is conspicuous swelling of the solitary glands; the mucous membrane is injected in patches and streaks, the summits of ridges and folds being particularly affected. The surface is covered by mucus streaked with blood. Inflammatory exudation then occurs: the mucous membrane becomes thickened and reddened, and the solitary glands, distended with "gelatinous mucus," stand out white and shot-like, surrounded by a red ring; the sub-mucous tissue is greatly swollen, and the muscular coat also may be involved. The infiltration of the mucous membrane with leucocytes continuing, ulceration occurs; this takes place first over the solitary follicles, small apertures being formed, through which, in time, the gland is discharged as a slough. The larger ulcers formed by surface disintegration of the mucous membrane deepen, their yellow floors being formed of the thickened sub-mucous tissue as a rule, but sometimes by the muscular or even peritoneal coat; in the latter event perforation may readily occur. The ulcers may have any form, and their longest diameter may be in any direction, but it is not uncommon to find them encircle the gut. The exudation may be sufficiently rapid to destroy considerable areas of mucous membrane, which then become detached as sloughs, leaving large, irregular, generally transverse ulcers of a grey or yellow colour. In the most acute form of the disease there is a remarkable thickening of all the coats of the intestine (the "diphtheritic form" of German writers), which feels firm and massive. The whole is not affected to an equal degree, so that folds and grooves are formed, or the thickening may be at first in patches. Where it is well marked, the intestine offers a solid resistance to the knife; its colour varies with that of the intestinal contents, and is generally yellow-grey, green, or black. The *microscopic changes* are extravasation of blood, and copious fibrinous and cellular infiltration into all the tissues. Gangrene eventually occurs; the eschars break down into shreds and scraps, the ulcers left being ragged, and of a dark-olive or brown

colour. The "diphtheritic form" appears to be identical with the gangrenous dysentery of Indian writers. In this form the lower part of the small intestine is liable to be involved, as is also the case in severe catarrhal inflammation going on to ulceration, but even in the most severe cases the morbid changes may be entirely confined to the large intestine. The ileo-colic valve may be destroyed, and the small intestine may then be invaginated into the large, and lead to acute obstruction. Recovery may take place by resolution in the early catarrhal stage before ulceration; afterwards, by granulation and cicatrization, leaving generally much long-persisting thickening.

Ætiology.—Dysentery is related on the one side to malarial fevers, and on the other to diarrhœa. It occurs especially in districts where malarial fevers are common, and disappears as they disappear. The connection is probably twofold—*i.e.*, the conditions which favour the occurrence of malarial fevers in communities also favour dysentery, and the condition of ill-health produced in individuals by malarial poisoning renders those individuals peculiarly prone to dysentery. Contamination of the drinking water with feculent matter, perhaps with matter derived from previous cases of dysentery, appears to be the most frequently operative determining cause; brackish water favours, if it cannot produce, the disease. Its prevalence is favoured by a high air temperature, and is stopped by frost, but a climate presenting great fluctuations of temperature is peculiarly dangerous. This may explain the frequency with which the disease has prevailed to a serious extent in some parts of Germany, in Sweden, Norway and even Iceland. It is not in any special sense a disease of towns, but rather the contrary, and is particularly apt to break out among troops engaged in campaigns; coarse, bad, ill-cooked and therefore irritating food is a factor of only less importance than bad water, and the combination of these two evils explains its importance as a "war pestilence." As a rule, the prevalence of the disease is very limited in extent, and it may be said to co-exist at many foci rather than to prevail over large tracts of country. Rarely, and for the last quarter of a century with increasing rarity, it has spread epidemically, and has thus caused a serious mortality in Germany, France, England and Ireland.

The personal habits or conditions of health which predispose to dysentery are

chronic alcoholism, chronic constipation (probably from the irritating effect of the hardened feces accumulated in the colon), malarial poisoning and new arrival in an endemic district. Surface chill from exposure to cold and damp, especially after exertion, is often the immediate determining cause of an attack. The evidence is against the disease being contagious, but, on the whole, in favour of its being communicable through water or food. It may occur at any age.

SPORADIC DYSENTERY as observed in temperate climates is generally of a comparatively mild type, but does not otherwise differ from the tropical endemic form of the disease.

CHRONIC DYSENTERY often follows an acute attack.

Symptoms.—The appetite is capricious; the tongue clean, red and glazed; there is abdominal tenderness and often masses of thickening may be felt. The patient suffers from painful colic and, if the descending colon and rectum be involved, from tenesmus. The stools are loose, and mucus, blood, or purulent matter is mixed with the feces.

Diagnosis.—Anal fissure and rectal ulcer are liable to be confounded with chronic dysentery, and sometimes exist as complications. In other cases an attack of acute dysentery is followed by cicatricial contraction of the gut, leading to chronic constipation or to obstruction.

Treatment.—If a case of *acute dysentery* can be controlled from an early stage, the results of treatment are, on the whole, more satisfactory than in most other diseases of like severity; this is owing to the almost specific action of ipecacuanha. The patient is put to bed, and from 20 to 30 grains of powdered ipecacuanha, suspended in syrup of orange-peel, are given in a small quantity of water; for the next three hours nothing else must be taken, but, if thirst be distressing, a little ice may be sucked. Nausea is generally experienced in an hour or two, and sometimes the patient vomits after two hours; if vomiting should occur earlier, so that the ipecacuanha is returned, 30 minims of tincture of opium may be given, followed by a fresh dose of ipecacuanha in half an hour. It is, however, undesirable to repeat the opium, and the ipecacuanha may preferably be given with bismuth, carbonate of sodium, camphor, chloroform or hyoscyamus. The second dose is given eight, ten or twelve hours after the first, and is rather smaller. When the first dose is given, a poultice or turpentine stupe should be applied to

the abdomen, or a sinapism over the epigastrium. The dose for an infant of six months is 1 grain; of one year, 2 grains; and 1 grain more for each additional year of age. Pregnancy is not a contra-indication; severe dysentery, if unchecked, usually causes a pregnant woman to abort, and death almost invariably ensues. The ipecacuanha is repeated night and morning until the tormina and tenesmus cease and the stools begin to be feculent.

During this period the diet should consist only of chicken, mutton or veal broth, meat jellies, and arrowroot or sago, with, as a stimulant, port wine or brandy. When dysentery is complicated by malaria, or is suspected to be so, 10 to 20 grains of quinine should be given at the commencement of the treatment, and subsequently doses of 10 grains in the intervals between the ipecacuanha. The malarial complication is said to be frequently responsible for vomiting when it occurs after ipecacuanha. In mild cases, a hot bath, followed by rest in bed, a few doses of ipecacuanha (gr. xv to xx); and subsequently, a draught containing castor oil (3j to 3ij) and opium may suffice.

In *chronic dysentery*, the first indication is change of air—in tropical cases, to the temperate zone. Woollen clothing must be worn, especially over the abdomen; the diet must be very bland and unirritating—often a milk diet for some time will be best. In bad cases, irrigation of the bowels with large quantities of a solution of nitrate of silver (3j to Oj) or alum may be efficacious. Even in the acute stage ice-water injections, with or without an astringent, have been advocated; about 3 or 4 pints will be required, and the injection must be suspended when pain comes on, and be resumed when it passes off.

DAWSON WILLIAMS.

DYSMENORRHŒA.—Some writers, adhering to etymology, understand by this term pain produced by the uterine contractions which expel the menstrual decidua; others extend it to any kind of pain which recurs once a month, and appears to depend on menstruation or ovulation. The latter use is adopted in this article.

1. Obstructive Dysmenorrhœa.—It has been maintained that not only in the majority, but in all cases dysmenorrhœa is due to mechanical obstruction, and that, owing to narrowing of the canal, the uterus has to contract more vigorously in order to force the blood past an obstacle, the pain being due

to these violent contractions. There is no doubt that obstructive dysmenorrhœa exists, as, after amputation of the cervix, gradually increasing menstrual pain may occur from progressive contraction of the orifice, which may ultimately produce complete atresia and retention of the menses. It may result from contraction of the cervical canal following the use of caustics, or from blocking of the canal by fibroids polypi or cancer. Obstructive dysmenorrhœa of this kind is rare, and does not date from the beginning of menstruation. But it is also supposed that obstructive dysmenorrhœa is common as a primary condition, dating from the establishment of menstruation, and that it is then due to stricture at either the internal or the external os (the advocates of this theory are not agreed as to where the stricture most commonly is), or to flexion of the uterus, the canal being flattened at the point of flexion. The writer has never seen a museum specimen, nor is he aware of any accurately measured case, of stricture (*i.e.*, organic narrowing) of the internal os. A very narrow external os, so that it will only admit a No. 1 or 2 bougie, or not even that, is occasionally seen, and in most cases is not accompanied by any dysmenorrhœa. Blocking of the uterine canal by flexion and dilatation of the uterine cavity behind the obstruction is sometimes seen in old women, in whom the uterine wall is thinned by atrophy; and also when the uterus is fixed in the bent position by adhesions, and therefore cannot contract properly; but it has never been found in a uterus which was free to contract, and had a wall of natural thickness. It is therefore very doubtful whether there is such a condition as primary obstructive dysmenorrhœa; and it is quite certain that if it exist it is extremely rare. The pain in genuine obstructive dysmenorrhœa does not reach a high degree of severity.

The *diagnosis* can only be made by physical examination. When an attempt is made to pass a sound, the canal is found to be blocked, and the sound cannot be passed. If a fine probe be forced past the obstruction, it is gripped, and its withdrawal is followed by escape of retained fluid.

The *treatment* is to open up a passage, either by dilating or by cutting, or by removing that which is blocking the canal, according to the nature of the case; and, when this is done, relief at once follows.

2. Spasmodic Dysmenorrhœa.—This

is a nervous disease; it is therefore sometimes described under the name of "neuralgic" dysmenorrhœa, but this term is better reserved for a different class of case.

The pain is due to spasmodic uterine contractions, the cause of which is not known. It is frequently coincident with deficient uterine development, and this seems to point out the direction in which preventive treatment should tend. Pain of this kind generally dates from the beginning of menstruation, but it may come on later, even after the patient has had many children, and in some such cases is due to fibroids. After it has been cured by dilatation, relapse may occur. When the disease has lasted long, ovarian pain is often added to the uterine pain, which gradually becomes longer in duration, until the patient is never free from pain. Should the patient marry early and become pregnant, the dysmenorrhœa will probably be cured. But frequently it is associated with lack of sexual desire and enjoyment, and even repugnance to and pain in sexual intercourse, and with sterility. In that case, if the dysmenorrhœa be cured, pregnancy may follow. This affection has been called by some "obstructive" dysmenorrhœa, and ascribed to stricture or flexion of the canal. But there is no stricture, the proof of this being that at the height of the pain a No. 7 or 8 bougie may be passed without being gripped, and when withdrawn no blood follows. It has been compared to labour, and ascribed to disturbed polarity; so that, instead of there being good contraction of the body and relaxation of the cervix, there is contraction of the cervix and imperfect painful contraction of the body. This view is plausible, but as yet no evidence has been brought forward to support it. This form of the disease occurs quite as often in uteri that are straight as in those that are bent. It has been ascribed to malformation of the cervix, the vaginal portion being conical and the os externum circular. These conditions are often met with in this disease, but in many cases they are absent, and the os externum is generally so large that if the hole were in a blood-vessel the patient would bleed to death in a few minutes.

The *diagnosis* rests mainly upon the following points:—(1) The exceeding severity of the pain. (2) The pain, although severe, is usually of short duration. (3) The pain is generally paroxysmal, depending on clonic contraction of the uterus, each paroxysm lasting a few

minutes. But the contraction is sometimes tonic, and the pain continuous. (4) It is not localized in one spot, but referred to the back and lower abdomen generally. (5) It is not relieved by lying down. Lastly, the proof of the diagnosis is that the pain is cured by dilatation of the cervix. The pain, as a rule, either begins with the flow or precedes it by a short interval. It may occur in the menstrual interval, and not during the flow, but this is very rare.

The *prognosis* is more favourable than in any other form of dysmenorrhœa except the obstructive. Cure is least likely in cases in which the disease occurs along with an imperfectly developed uterus.

Treatment.—Dilatation of the cervical canal is usually the best treatment. There are various ways of effecting this, but it is best performed with metal bougies. No. 6 can usually be easily passed, and then successive sizes can be introduced one after the other until a size is reached which is gripped by the canal. Each bougie should be left in until the pain caused by its introduction has subsided, which will usually be in two or three minutes. If the pain should not subside within ten minutes, the bougie should be withdrawn, and further dilatation desisted from. The patient should afterwards keep her bed for the rest of the day. Some think that relief is attained with greater certainty by incision, but no facts have been published in support of this opinion. Those who practise incision of the external os for the relief of this condition generally combine with it some kind of dilatation of the os internum. But if there be distinct deformity of the vaginal portion, with narrowness of the os externum, it will be well to combine division of this part with dilatation of the os internum. If the dysmenorrhœa be associated with ovarian pain, it is well to keep the patient in bed until the next period is over. In the experience of the writer, about one-fourth of the cases of primary dysmenorrhœa can be cured by dilatation alone. The best medicinal treatment consists in the administration of anti-pyrin, of which three doses of 15 grains each may be given, and of diaphoretics, such as liq. ammon. acet. ℥j, or amm. chlorid. ℥j, or mist. guaiaci ℥j. Hot applications to the hypogastrium and hot gin-and-water are popular domestic remedies. Opiates should on no account be given, nor should alcohol be recommended. If the disease be so severe as to interfere with the patient getting her living or

fulfilling her social duties, and other treatment fail, it can be cured by removing the ovaries, which is preferable to teaching the patient to resort to opium or alcohol.

3. **Membranous dysmenorrhœa** is due to the menstrual decidua, instead of undergoing disintegration, being shed in one or more large pieces, which obstruct the cervical canal, and so cause painful menstruation. This form is literally obstructive, but the obstruction is in the flow, and not in the uterus. The membranes shed usually show appearances of slight inflammation, and hence this disease is commonly regarded as a form of endometritis. Some cases are really instances of monthly abortions, their nature being shown by there being neither passage of membranes nor pain while the patient is leading a single life. The disease occurs at all periods of menstrual life in the virgin, the married, and the parous.

The *diagnosis* is made by finding the membranes. The affection is probably much commoner than is generally supposed, because, in the majority of cases, the patients are unaware that they pass membranes until they are asked to examine the discharge. Pieces of membrane can be distinguished from clots by their being, when unfolded (for they are usually passed rolled up), smooth on one side (the inner) and dotted with the openings of the utricular glands, whilst on the other (the outer) they are rough. In case of doubt, a microscopic examination should be made.

Practically nothing is known as to its *etiology*.

The *treatment* of membranous dysmenorrhœa is unsatisfactory, and there is no treatment from which success can be predicted. Arsenic has been given, and perchloride of mercury sometimes succeeds. Intra-uterine applications generally fail to do good. The best treatment consists in the use of tonics to improve the general health and increase the resistance of the nervous system to painful impressions. In the virgin local treatment should not be practised. In the married the cervical canal may be dilated; this may relieve the pain, although it cannot be relied upon to cure the affection.

4. **Ovarian dysmenorrhœa** is the form in which the pain is not in the uterus, but in the ovaries. This kind of pain may be due to ovulation, or to the general congestion of the pelvic organs which precedes menstruation. Nothing is known about the changes in the ovary that give

rise to the pain. The characters of the pain are—(1) it is localized, usually at a spot about 2 inches internal to the anterior superior iliac spine; (2) it is neither severe nor paroxysmal, but gradual in onset and subsidence, may last some days, and is usually described as “aching” or “burning”; remissions and exacerbations may occur; (3) it is relieved, but not altogether removed, by recumbency and is aggravated by exertion, alcohol and constipation.

The *diagnosis* is made by the characters of the pain, combined with tenderness in the situation of the ovary, either on pressure abdominally, per vaginam, or per rectum.

The *prognosis* depends chiefly on the duration of the disease. If of only a few months' date, it can generally be cured; if it have lasted for years, the prospect is unfavourable.

Etiology.—Its most common cause is child-bearing and lactation, together with depressed conditions of health, such as anæmia and nervous exhaustion. Among other causes are gonorrhœa, the excessive use of alcohol, and morbid sexual excitement. Sometimes it remains after the acute exanthemata. It may be secondary to some disease of the uterus, such as spasmodic dysmenorrhœa, retroflexion, or inflammation of cervix.

The *treatment* consists in the cure of any disease of the uterus that may be present, and the improvement of the general health by the removal of anæmia, if present, by iron, and by the promotion of appetite and sleep; rest in the recumbent position; laxatives; the avoidance of alcohol; counter-irritation to the iliac regions either by flying blisters or lin. iodi. Opiates should be avoided. If hypnotics be needed, the bromides are the best.

5. **Intermediate dysmenorrhœa** is a term which can only be defended as clinically useful to denote a class of cases in which there is pain, lasting a few days, which recurs regularly once a month, but not at the menstrual period. The characters of the pain usually warrant the belief that it is ovarian, and its monthly recurrence, that it is caused by the process of ovulation. There is evidence that the maturation and bursting of Graafian follicles may take place at any time between two menstrual periods; and, therefore, if this process be painful, the pain may have any relation in point of time to the menstrual flow. The treatment of such cases is that of ovarian dysmenorrhœa.

6. **Congestive Dysmenorrhœa**.—This

term has been applied to more than one class of case.

(a) *Primary, or initial, congestive dysmenorrhœa.*—This comprises cases of menstrual pelvic pain which do not fall under any of the preceding categories. The pain is not of great severity, not localized in either ovary, not paroxysmal, and is usually relieved by lying down. No membranes are found, and no abnormal condition is discovered on examination. In such cases, if the flow be scanty and the patient plethoric, leeches may be applied to the groins or perineum, saline laxatives given, and the recumbent position maintained. If the flow be profuse, the latter measures only are indicated.

(b) *Acquired Congestive Dysmenorrhœa.*—This is a well-marked form, but not common in the virgin. A patient, who has previously menstruated without pain, after a chill or some disturbance of health or perhaps without any obvious cause, finds menstruation getting more scanty and attended with increased pain. In such cases it is a reasonable hypothesis that the pain occurs because there is not enough blood lost to relieve the menstrual congestion.

The success of *treatment* bears out this view of the pathology. Recent cases—that is, of not more than six months' duration—can almost always be cured by local depletion. Four or six leeches should be applied to the cervix (or to the groins or perineum in a virgin). In the interval the patient should insert a glycerin pessary (gelatin gr. xx, glycerin ad ℥ij) night and morning, having first used a warm vaginal douche. Laxatives should be given. In a quite recent case, relief will probably be complete. In cases of longer duration, the first depletion may only benefit for a short time, but after each subsequent abstraction of blood the freedom from pain will last longer. It is only in cases of very long standing that, when combined with rest, this treatment fails to afford relief.

(c) *Secondary congestive dysmenorrhœa* includes those cases in which the pain is due to the aggravation of some morbid condition by the menstrual congestion. In uterine displacements, pelvic peritonitis, diseases of the Fallopian tubes, vaginitis, hæmorrhoids, movable kidney and many other conditions, all the symptoms are usually worse at the menstrual period. Investigation will detect its cause. The *treatment* is that proper for the disease underlying the complaint.

6. *Neuralgic, or Neurotic, Dysmenorrhœa.*—There is a class of patients

in whom the nervous system is comparatively unstable, who are easily upset by trifling causes, are very sensitive to pain, and liable to neuralgias of all kinds. In them the vascular and other disturbances accompanying menstruation may evoke manifestations of nervous disturbance in remote parts, with or without pelvic pain. There may be headache, facial neuralgia, nuchal pain, epigastric pain with or without vomiting, intestinal colic followed or not by diarrhœa, ocular symptoms, temporary mental derangement or emotional excitement. This form of dysmenorrhœa is identified, first, by the irregular character of the morbid sensations, which are diffused, not confined to the pelvis, and do not follow a regular type; and secondly, by the kind of patient in whom it occurs—*i.e.*, in weakly, nervous, anæmic, often badly developed subjects.

The only *treatment* that can do any good is of a kind beneficial to the nervous system—tonics, iron, change of air and scene, regular hours and good food. Removal of the ovaries in such cases may sometimes stop menstruation, but does not remove the pain.

G. E. HERMAN.

DYSPEPSIA, ACUTE.—Acute dyspepsia is generally traceable to errors in diet; it occurs at all ages; it is more frequent in dark-complexioned than in fair persons, and is especially frequent in the gouty.

The *symptoms* are headache, frontal, occipital, or general, anorexia, nausea, and vomiting. The tongue is coated or plastered, and the breath foul. Food cannot be retained. Occasionally there are chills, rigors, epigastric pain and slight icterus. The vomited matters usually contain more or less bile. The bowels are generally confined.

The *prognosis* is favourable; the affection usually subsides under appropriate treatment in a few days.

Treatment.—The administration of food must not be attempted till vomiting ceases. Then a breakfast-cupful of beef-tea, alternately with the same quantity of milk, thin gruel or arrowroot, should be given every three or four hours. A little toast may be allowed, but no other solid food; soda-water is permissible. The diet is to be extended cautiously as the symptoms subside and the tongue clears. Alcoholic liquors are to be avoided. Pil. hydrarg. in doses of 3 to 5 grains, or 2 to 4 grains of calomel, should be taken at once, and mist. sennæ co.

3j-ij three hours later. If vomiting be troublesome, ac. hydrocyan. dil. ℥ij, with sod. bicarb. gr. xx, should be given in 3j of plain water every six hours.

ISAMBARD OWEN.

DYSPEPSIA, CHRONIC.—This is a term applied indifferently to all forms of chronic disturbance of the gastric functions which are not traceable to organic or reflex causes or to direct irritation.

These disorders of digestion are variously referred to chronic catarrh of the mucous layer, to enfeebled action of the muscular coat, to exaltation of sensation, to perversion of secretion, to the presence of abnormal ferments, to deficient action of the liver causing portal congestion or to several of these causes combined.

The catarrhal forms are usually distinguished as "irritative" dyspepsia; those thought to be due to enfeebled action of the muscular coat or secreting glands, as "atonic" dyspepsia.

The *symptoms* most commonly recognized as due to these forms of gastric disturbance are sensations in the epigastrium, varying from slight uneasiness and a sense of "sinking" to "weight" or "fulness" or to actual pain, which often extends to the interscapular region. These sensations usually commence from a few minutes to a few hours after taking food, and pass away as the stomach empties itself, but sometimes they are constant throughout the day, and in a certain proportion of cases most acute when the stomach is empty, food bringing relief. The appetite is usually diminished, the tongue swollen or reddened, and covered with a slight white fur. The patient is generally languid and depressed, his temper is irritable, and he is troubled with eructations. It is less usual to find the pain localized in the mid-sternal, cardiac, hepatic, splenic or umbilical region. Flushing of the face after meals, oppression of breathing, palpitation of the heart and headache, usually occipital, are symptoms sometimes complained of. Nausea, retching and vomiting are not infrequent. A somewhat rarer manifestation of the disorder is a craving for food at a time when the stomach is full, which is known as *bulimia*. In a few cases the patients describe shooting pains in the shoulders, neck or arms; and still more rarely numbness of one or more digits, apparently caused by a reflex vaso-motor spasm. The bowels in all cases are liable to be confined; diarrhoea rarely occurs. The epigastrium is usually found to be more or less tender on pres-

sure, the tenderness being fairly equally diffused.

The "irritative" forms of dyspepsia are especially indicated by acuteness of the pain, redness and furring of the tongue, marked loss of appetite, nausea and liability to vomiting. The purely "atonic" forms, on the other hand, are recognized by the dulness of the pain, the flabbiness and pallor of the tongue, the presence of appetite and the absence of nausea. The distinction between these forms of dyspepsia is, however, very indefinite in practice, and probably a purely "atonic" condition of the gastric wall is rarely met with. The products of disordered digestion can hardly fail to excite local irritation in some degree.

The *prognosis* is generally favourable, but dyspepsia is often obstinate and may last during life. In persons predisposed to tubercle it should be looked upon with suspicion, as it is sometimes premonitory of phthisis.

Pathology.—The pathology of these disturbances is mainly conjectural, and they have no recognized morbid anatomy. Torulæ and sarcinæ are sometimes found in the stomach during their continuance.

Ætiology.—Chronic dyspepsia is undoubtedly due in some cases to anæmia, to debility from various causes, lithiasis, diabetes, chronic renal disease, chronic heart disease (causing passive congestion), hysteria, habitual constipation and habitual cough. It may be traced in some cases to loss of teeth, to a sedentary life, errors in diet, the abuse of alcoholic liquors, condiments, tea or tobacco, but it frequently occurs without any discoverable cause.

Treatment.—The first point to be attended to is a strict observance of proper intervals between meals, and to forbid the taking of food or drink between the regular times. The rate of digestion in the subjects of dyspepsia is usually slow, and an interval of five hours will generally be required after a moderate, and one of six or seven after a full, meal. The patient must be warned not to mistake the "sinking" or craving of an irritated stomach for a demand for food. It is also necessary to restrict the amount of food taken as nearly as possible to physiological requirements, so as to throw no more work than is necessary on the disturbed organ. Unless much irritation of the stomach be present, the tendency of the dyspeptic is nearly always to exceed the requirements of the system.

A specific prohibition of sticky, heavy or greasy articles of food, and in "irri-

tative" cases of highly seasoned dishes and condiments, is necessary, as such are much affected by many dyspeptics. Pastry, cheese, pork, salt meats, crabs and lobsters, uncooked vegetables and fruits are especially apt to disagree, and should be categorically forbidden. In many cases potatoes are found to be inadmissible. Butter may generally be allowed in moderation. Constant regard must, however, be had to *idiosyncrasy* in matters of diet, which is often singular and unaccountable.

Alcoholic liquors should generally be forbidden in "irritative" cases. Light wine or beer is sometimes beneficial in "atonic" cases, and, in the aged, small quantities of spirits are at times found to stimulate a failing digestion. The stronger wines are seldom of service. *Alcoholic liquors should never be ordered for women in dyspepsia without urgent cause. The practice of taking them to relieve epigastric "sinking" is one of the most prolific sources of female drunkenness.*

It is as well to prohibit the use of strong tea, which dyspeptic women in particular are very apt to drink to excess. Coffee and weak tea are matters of individual idiosyncrasy, and their admissibility can only be decided by experiment. Cocoa is well tolerated by many dyspeptics. If the bowels be costive, they should be regulated, not by the occasional administration of strong purgatives, but by the use of habitual mild laxatives, to which small amounts of mercury, podophyllin or euonymium may be added, if the tongue show a tendency to display a loose coating. *Cascara sagrada*, in doses carefully regulated so as to avoid griping and irritation, is a valuable laxative in "atonic" cases. Daily injections of a drachm of glycerium will sometimes procure a regular alvine action.

It must be carefully ascertained whether the teeth are in working order and whether mastication is properly performed. In elderly people a set of artificial teeth may be the only treatment required. Anæmia, debility, lithiasis, diabetes, disease of the heart or kidneys, or hysteria, if present, must be combated by the treatment appropriate to those conditions; and, if sedentary pursuits appear to have induced the dyspepsia, regular, but not excessive, exercise should be ordered.

In "irritative" cases relief is often afforded by the salts of bismuth. They may be administered three times a day, just *after* a meal, bism. subnit. et mag. carb. levis āā gr. x, suspended by a

drachm of mucilage in aq. menth. pip. ʒj. If there be much pain, liq. morph. bimec. ℥ij-v, or tr. belladonnæ ℥vj, or tr. hyoscyami ʒss, may be added with advantage; and ac. hydrocyan. dil. ℥ij should be introduced if nausea or vomiting be present. The morphine should not be continued for more than a fortnight if it can be avoided.

In "atonic" cases the best results are obtained from a combination of an acid with a vegetable bitter: *e.g.*, 10 to 15 minims of a dilute mineral acid, flavoured with 1 drachm of syrup of orange peel, in infusion of quassia, calumba, or gentian, taken three times a day *au hem* after a meal. Liq. strych. hydrochlor, ℥ij, or tr. nuc. vom. ℥x, may be added to, or substituted for, the bitter infusion, and stimulating aromatics, such as clove, nutmeg or ginger, are at times of service. In some cases it will be found that an alkali (liq. potass. ℥x, or sod. bicarb. ʒj) alone, or in combination with a bitter, affords more relief than the acid. There is no trustworthy indication as to the cases in which acids or alkalies respectively are preferable.

In "irritative" cases flatulence is often troublesome. It is best combated by the use of anti-ferments. One grain of carbolic acid, or 1 minim of creasote, or $\frac{1}{2}$ grain of thymol may be given in pill twice a day, or ac. sulphurosi ʒj in 3 ounces of water once or twice daily. In "atonic" cases aromatics and bitters are the best preventives of flatulence.

Pepsin, to the extent of 5 grains in pill or powder, or a teaspoonful of one of the advertised liquid preparations of pepsin given after meals, is sometimes found to aid digestion in "atonic" cases. Extract of malt (a table-spoonful twice a day after meals) is also of service in certain cases. Small doses of arsenic are not infrequently of benefit in "atonic" cases, especially when general nervous debility is present, and the dyspepsia appears to be but a symptom of the general state. In severe cases a much more restricted diet may be required for a time, the case being treated practically as one of mild gastritis.

ISAMBARD OWEN.

DYSPHONIA (Hoarseness) is brought about by much the same set of conditions as give rise to aphonia (*q.v.*), but they are of a less pronounced character. Hence, hoarseness frequently precedes or follows aphonia. The most frequent causes of hoarseness are conditions which produce irregular vibration in the

vocal cords, as, for example, inflammatory conditions of the cords, adherent mucus, new growths or ulceration, and paralysis of one cord.

DYSPPŒA signifies a difficulty of breathing, from whatever cause it may arise. It may be due to laryngeal or

tracheal obstruction, to lung disease, such as emphysema, phthisis or pneumonia, to pleurisy or some affection of the heart, or may result from anæmia. If the dysppœa be so urgent that the patient can only breathe when supported in the upright position, it is termed "orthoppœa."

E

ECCHYMOSIS is the name given to an effusion of blood into the subcutaneous tissues, whether as the result of violence or from disease. When large, there will be considerable swelling, and the part soon becomes purple, the colour gradually changing to a brown and ultimately passing through green and yellow before the skin regains its natural appearance. Very small extravasations of blood do not cause any swelling; they may be known by their purple colour, and by the fact that they do not fade on pressure. They may be of any shape or size: when small and round, they are called *petechiæ*; when occurring in lines, *ribices*.

ECTHYMA is a term used to designate a pustular eruption the lesions of which consist of large, isolated, flat, flaccid pustules on an inflamed, hard base, followed by thick, dark crusts, leaving deep pigmentation and sometimes superficial scarring.

The affection occurs only in badly fed and cachectic individuals, especially in children and old persons, and is now recognized as being almost invariably an epi-phenomenon in cases of scabies, pediculosis, impetigo, eczema, dermatosyphilis or any other pustulating dermatoses. Very exceptionally, cases answering to the above description appear to occur independently and justify the retention of the name. Any soothing local application is effectual in bringing about cure, but constitutional treatment alone is of service for preventing fresh outbreaks.

J. J. PRINGLE.

ECZEMA (Moist Tetter) may be defined as an acute or chronic, non-infective, catarrhal inflammation of the skin.

It is characterized, in its most advanced stages, by the successive development of erythema, papules and vesicles or pustules, with serous or purulent discharge, accompanied by itching or burning, and

dependent mainly on constitutional causes.

It is the commonest and most important disease of the skin and frequently complicates other skin affections, as the result of scratching or irritating applications. Pathologically and clinically it is a typical inflammation of the skin, and names, still useful for descriptive purposes, have been attached to its various phases, which were previously regarded as separate forms of disease. The term *eczema erythematousum* denotes its mildest form, in which the skin is reddened, slightly swollen, infiltrated and tense from active congestion; the colour of the patches is more vivid, and their edge less well defined, than in true erythema. Soon, increase of hyperæmia with infiltration of the papillæ and rete Malpighii with serum and migrated leucocytes, results in the formation of minute intensely itching papules of a deep-red colour and firm consistence, arranged in irregularly shaped groups (*E. papulosum*). At this stage the process may be arrested. The condition now somewhat resembles a lichen, and, indeed, was formerly described as lichen simplex; the arrangement of the papules is, however, different, and careful examination with a lens seldom fails to discover incipient vesication at some part of the eruption.

Usually, the process advances; serous exudation accumulates between the comparatively loosely connected cells of the rete mucosum, and raises the cuticle to form vesicles containing clear fluid, constituting the most constant and characteristic phase of the disease, *E. vesiculosum*. With increased duration and intensity of the inflammatory action, the fluid in the vesicles becomes cloudy from increased diapedesis of leucocytes, or frankly pustular (*E. pustulosum*), the pustules being usually of larger size than the preceding vesicles. Frequently, however, pustulation does not ensue, but the cuticular covering of the vesicles yields

under the pressure of the rapidly exuded serum, and the rete mucosum, covered with exudation, is exposed. Large, raw, "weeping" surfaces, studded with red points, are formed by the coalescence of these excoriations, and to this common and typical condition, which may also succeed *E. pustulosum*, the term *E. madidans* or *E. rubrum* is applied.

The fluid discharged from such surfaces has the familiar property of stiffening linen, and, if it does not escape, macerates the surrounding skin, causing extension of the disease *per contiguitatem*, and dries up to form crusts and scabs, the colour of which varies according to the amount of the contained cell elements. If these are small in number, the crusts are thin and pale-yellowish in colour (*E. crustosum*); if numerous, and especially if bleeding occur from the exposed capillaries, the crusts are thick and dark in colour (*E. impetiginosum*). The latter form occurs with special frequency in strumous children on the scalp and face, and the crusts may acquire a peculiarly offensive odour from the decomposition of sebum poured out in excessive quantity as the result of inflammatory implication of the sebaceous glands.

The return to health is first evidenced by diminution in the amount of exudation and progressive extension of epidermic cells from the edge over the surface of the excoriated patch. Even when this process is complete, the skin remains thickened, indurated and reddened, and excessive cell formation continues on the surface of the patch, resulting in the formation of whitish, more or less adherent scales of shed epithelium (*E. squamosum*), a condition which may prove very persistent.

If situated upon parts subjected to much movement (*e.g.*, the hands, articulations), deep, painful cracks or fissures are liable to form in the hardened skin in a direction similar to that of its normal folds, and transverse to the direction of the principal movements of the part (*E. rimosum* or *E. fissum*). Where a tendency to passive congestion exists, as in the lower extremities, recovery is naturally slower than where the circulation is active, the papillæ of the skin may permanently hypertrophy, and cause general or limited warty outgrowths (*E. hypertrophicum*, *E. verrucosum*). There is also a special tendency to chronicity around hair follicles, where irritable, acuminate papules may persist for prolonged periods (*E. folliculare*). True eczema probably

never causes scarring, and the pigmentation left by it soon disappears.

The pathological histology of the disease may be inferred from the foregoing sketch.

In the *diagnosis* of eczema, *locality* is an important factor; it is common wherever skin and mucous membrane join, wherever hair and sebaceous or sweat glands abound, and where the skin is soft, thin, or thrown into folds, *e.g.*, the flexures. The value of itching, especially in the vesicular and papular forms, or of burning as diagnostic points has already been mentioned. Polymorphism, due to the simultaneous existence of various phases of the disease, is as marked a characteristic of eczema as of syphiloderma, and the same necessity arises for complete examination of every patient. Difficulties in diagnosis chiefly arise from the arrest of the morbid process in the earliest, or its persistence in the latest stages; in the former case evidences of vesication, in the latter of serous discharge, will seldom be wanting; even the scales of the most obstinate *E. squamosum* show dried gummy material on their deep surface.

It is of practical importance to differentiate true eczema from local dermatitis the result of topical irritation, although such a distinction is arbitrary and convenient rather than scientifically accurate. The salient points of contrast to eczema presented by a dermatitis are—it is local, and confined to the region directly affected by the irritant, the intensity is directly proportional to that of the irritant, and the further progress is at once arrested by removal of the irritant. A connecting link between dermatitis and eczema—thus conceived—has recently been recognized in the fact that a very large number of eczemas are secondary to the decomposition of sebum or sweat, secreted in excessive quantity and undergoing putrefactive changes—probably under the influence of specific micro-organisms, hitherto undetermined—as the result of which they become chemical irritants to the skin (*E. seborrhæicum*, *sweat eczema*). The point has an important bearing on treatment.

Differential Diagnosis.—Acute eczema is liable to be mistaken for erysipelas, local dermatitis, or miliaria rubra; papular eczema for lichen or multiform erythema; vesicular eczema for herpes or bullous erythema; pustular eczema for scabies, impetigo, pustular syphiloderma, folliculitis, or tinea favosa; and squamous eczema for psoriasis, pityriasis rubra,

lupus erythematosus, seborrhœa, and tinca tonsurans.

Prognosis.—Eczema is seldom dangerous to life. Children are frequently reduced to a very low state by it, but rarely die. Occasionally, in old persons suffering from chronic Bright's disease, the condition becomes universal, and death results. Acute eczema tends either to relapse at regular intervals after apparent recovery, or to become chronic with occasional acute exacerbations. The not infrequently observed alternation of eczematous attacks with bronchial catarrh or asthma and with gastric catarrh is the basis of the popular belief, still shared by some medical men, that the rapid cure of a skin disease may result in more dangerous affections of the internal organs from metastasis. The most experienced dermatologists have pronounced such fears chimerical.

The *etiology* of eczema is a problem of the greatest difficulty and complexity, which is far from having received complete elucidation.

Young children and old persons are specially liable to eczema, as they are to catarrhal affections of the bronchial and other mucous membranes. Men appear to be more frequently affected than women, probably because they are more exposed to the various causes of local dermatitis in the course of their occupations. An hereditary tendency to the disease certainly exists in the form of an inherent susceptibility to irritation by mechanical, thermic or chemical agents, not noxious to healthy skins; thus the sun's rays, cold winds, soaps, or vaccination may cause eczema in one child only out of a number subjected to absolutely identical influences, no demonstrable morphological peculiarity of the skin being present. To invoke an "herpetic" or "dartrous" diathesis as explanatory of such facts is only to throw the argument one step further back.

The association of eczema in children with scrofula, dentition, improper feeding or worms, in adults with rheumatism, gout and "the gouty condition" (including lithiasis, oxaluria, renal inadequacy, senile glycosuria), with dyspepsia, chronic constipation, uterine disorders and alcoholism, is so frequent as to suggest strongly a causal connection. This view is also strengthened by the markedly beneficial influence on the disease of remedial measures applied to those various concomitant conditions, but the essential nature of the connection is unknown, and it is probable that there is

a mutual dependence on a common cause, rather than interdependence. There is no more fertile obvious source of eczema than depressed conditions of the nervous system, such as result from worry, anxiety, overwork, neurasthenia and anæmia (especially when attending over-lactation); this fact, the severity of the itching, and the marked symmetry of the lesions all give colour to the theory now gaining ground, that changes in the central nervous system, the nature of which is beyond our present knowledge, probably underlie all cases of true constitutional eczema. Treatment recently advocated in the form of counter-irritation over the spine, based on this theory, appears to be attended with decided success.

General Treatment.—Predisposed persons do well to adopt certain general preventive measures. Rough woollen clothing, exposure to cold winds, sea air or excessive heat, or to various noxious substances used in many trades, copious sweating, dirt, the frequent intermittent application of water, especially of salt water, and the use of irritating soaps or cosmetics are to be avoided. Proper dietary restrictions ought to be observed.

Acute eczema in the earlier stages is best treated by complete rest, liquid diet, saline aperients and diuretics, and locally by protective dusting powders (oxide or oleate of zinc, bismuth, prepared chalk, cimolite, salicylated starch); a few drops of antimonial wine are often useful in robust persons. When the discharge is profuse, and burning or itching severe, cold lead lotions (*e.g.*, liquor plumbi subacetatis dilutus, B.P.), applied on soft linen rags and frequently renewed, are valuable. An excellent lotion, which combines the qualities of a cooling application and of a slightly greasy dressing, is made by adding a drachm of liquor plumbi subacetatis to an ounce of fresh milk. Poultices and water dressings covered with oiled silk are specially injurious.

The treatment of chronic eczema is far more important and more difficult, and the value of personal experience in its management is paramount; nor will any severe or old-standing case recover without persistence in the line of treatment adopted. The diet ought generally to be of a simple and unstimulating description; salt meats, pastry, cheese, coffee, peppery condiments, strong wines and malt liquors ought scrupulously to be avoided; in anæmic women and old men a glass of sound wine with meals is, however, often to be recommended. Milk

vegetables, white fish, stewed fruits and farinaceous foods are generally suitable, as are alkaline table waters. Frequent washing with soap and water is deleterious, especially if the water be "hard," as it produces maceration of the delicate cuticle. Water boiled with bran, barley or oatmeal, and strained, is less noxious, and rice-milk or thin gruel are excellent cleansing and soothing substitutes for water. When soap becomes permissible, that manufactured in Hamburg with a super-fatty basis is to be strongly recommended. Sulphurous baths (Strathpeffer, Harrogate, Bagnères, Aix-les-Bains) are sometimes of advantage in very chronic cases with dryness and thickening of the skin without much irritation.

The concomitant dyspeptic or other troubles must be treated according to their predominant symptoms. It will suffice here to state that attention to the regular action of the bowels appears to be of special importance, and that cod-liver oil is as valuable for the eczema of children as the various preparations of iron are for anæmic patients.

Opium frequently aggravates the itching, and its use is to be avoided for the treatment of that symptom in favour of chloral or the bromides in children, henbane or the tincture of hop in old persons. A dose of sulphate of quinine at bedtime is often effectual in producing a good night's rest.

The utility of arsenic is strictly limited; it is distinctly deleterious in the acute stages, when the disease is extensive or itching severe. Its effects are frequently strikingly beneficial in old-standing cases with much infiltration and dry scaling, and in young children, provided the digestive functions be in good order. The dose should be small at first, then cautiously increased. The liquor arsenicalis is the best preparation, and must always be largely diluted and given on a full stomach. Pitch pills or turpentine internally are sometimes useful in very chronic cases if the general health be unimpaired.

The removal of decomposing and irritating matters from the surface of the skin by vigorous washing is a necessary preliminary to the successful treatment of all eczemas which depend upon the presence of such a condition. All cases resulting from seborrhœa and hyperidrosis—and they are numerous—must be treated thus, and the procedure repeated as often as the re-accumulation of sebum or sweat necessitates. The subsequent

local treatment is the same as for other forms of eczema, and may be said to have for its objects—(1) the diminution of hyperæmia and exudation, (2) the relief of itching and burning, (3) the stimulation of indolent chronic patches.

These objects are attained by the use of lotions, ointments and pastes; broadly speaking, lotions are most suitable for moist, ointments and pastes for dry surfaces. Lotions are also generally preferable for exposed parts, for children, and in warm weather; their method of application has been already described. Solutions of the salts of lead and of borax (3j ad 3iij), are those most generally useful for the more acutely hyperæmic and profusely discharging forms. Dilute solutions of carbolic acid (gr. v-xv ad 3j), liquor carbonis detergens (3j-5j ad 3viii), thymol or naphthol (gr. v-xx ad 3j with a little spirit) often relieve itching. The lead and milk lotion already mentioned is useful for more chronic, slightly discharging surfaces, as are thick lotions containing protective soothing substances in suspension with mucilage or tragacanth, *e.g.*, the oxide (gr. x-xxx ad 3j) and carbonate of zinc (gr. xxx-xl ad 3j), subnitrate of bismuth (gr. v-xv ad 3j), and chalk; applied with a camel's-hair brush, and allowed to dry on the part. Glycerine is apt to irritate, but may be used as a vehicle when slight stimulation is indicated, when lotions containing sulphur are also useful, especially for limited scaly patches. A valuable formula is—R Sulphur. precip. gr. xx, ætheris ℥xxx, spir. lavandulæ ℥xx, glycerin. ℥xv, aq. rosæ ad 3j. In the same circumstances Hutchinson's lotion (liq. carbonis detergens 3ijss, liq. plumbi subacetat. 3ss; 3j in a pint of warm water, to be applied with a sponge) is often of great service.

Ointments are the most generally useful applications; although often disagreeable, they soften and protect the skin, cool it by facilitating evaporation, and act with comparative rapidity, while their effects are durable. Failure to obtain a cure by them is often the result of an imperfect mode of employment rather than of faulty selection of the remedy. Crusts must first be removed by the application of cold starch poultices, soaking with olive oil or a solution of bicarbonate of soda (gr. xxx-5j ad 3j), then the exposed surface is dried with absorbent wool. The ointment must be smeared over the part, and pretty thickly and evenly spread over properly cut strips of soft linen, and applied like a loose band-

age, the edges overlapping. The "many-tailed" form of bandage is handy for the extremities. The whole should then be covered and fixed in position with a flannel roller. For the face, a flannel mask may be necessary, especially for children. Usually, one change of dressing daily suffices, but two changes in the twenty-four hours may be expedient if crust formation is rapid. The oxide and carbonate of zinc and lead, the subnitrate of bismuth, or the pure oleates of these metals, obtained by double decomposition, are the most generally useful remedies, made up with benzoated lard, vaselin, or lanolin, and the addition of salicylic acid (2 per cent.) is often advantageous.

The following formulæ may all be recommended:—(a) Ung. zinci oxidi, B.P. (b) Ung. zinci oleati, B.P. (c) R Zinci carbonatis gr. xxx- $\tilde{a}\tilde{a}$, adipis benzoati $\tilde{3}\tilde{j}$. (d) R Emplastri plumbi $\tilde{3}\tilde{x}$, olei olivæ $\tilde{O}\tilde{j}$; heat and mix thoroughly, then add olei lavandulæ $\tilde{3}\tilde{i}\tilde{j}$; this was much used by Hebra. (e) Bismuthi subnitratis vel oleatis gr. x-xxx, adipis benzoati et vaselini $\tilde{a}\tilde{a}$ $\tilde{3}\tilde{s}\tilde{s}$. (f) Ung. zinci oxidi, vaselini albi $\tilde{a}\tilde{a}$ $\tilde{3}\tilde{i}\tilde{i}\tilde{j}$, acidi salicylici 2-4 per cent.; this forms a specially useful ointment, to which starch may be added up to 50 per cent., according to the consistence desired. (g) R Boracis gr. xx, adipis benzoati $\tilde{3}\tilde{j}$. On obstinate, pustular forms and old chronic patches mercurial ointments appear to have an "alterative" as well as a stimulant action, and those of the subchloride, perchloride, ammonio-chloride, nitrate and red or yellow oxides, found in the B.P., are all valuable preparations, which ought, however, generally to be diluted or combined with others. Vigorous washing with an alcoholic solution of soft soap (saponis mollis, alcohol rectif. $\tilde{a}\tilde{a}$ $\tilde{3}\tilde{v}\tilde{j}$) before the application of the ointment is a useful and painless stimulant measure in many of these cases. The various forms of "salve-muslin" recently introduced by Unna, of Hamburg, and manufactured by Beiersdorf, of that city, are convenient for the continuous application of ointments. The zinc-ichthyol salve-muslin is specially useful in chronic, scaly eczema.

Pastes resemble ointments in their mode of application, but are only useful to scaly patches; they dry up, forming an adherent coating to the skin. A useful basis consists of equal parts of lanolin, vaselin, oxide of zinc and starch, with which tars, naphthol, resorcin, ichthyol or salicylic acid, in proper proportions can be conveniently combined. A gene-

rally useful application in sub-acute and chronic eczema is Unna's glycerin jelly, which is thus constituted:—Glycerin 30 parts, gelatin 15, oxide of zinc 10, water 40. When these are melted together a gelatinous mass is formed, which is liquefied when the vessel containing it is immersed in boiling water, and is applied to the skin with a stiff brush, a layer of cotton-wool being superimposed to form an impermeable but pliant coating, which is easily removed with warm water. It is advisable to diminish serous oozing by cold starch poultices containing 2 to 3 per cent. of boracic acid before applying the glycerin jelly.

The effect of tars upon old scaly patches is often beneficial, but so capricious that it is a wise rule to begin by applying them to a very limited region in order to test their effects. The liquor carbonis detergens may be conveniently incorporated with one of the foregoing ointments in the proportion of $\tilde{3}\tilde{j}$ to $\tilde{3}\tilde{i}\tilde{i}\tilde{j}$, and increased slowly if tolerated.

Finally, the most obstinate cases may be treated by caustic applications (*e.g.*, tincture of iodine, saturated solutions of caustic potash or nitrate of silver) applied with caution, or by blisters, the thickened epidermis being removed afterwards by rubbing with bran, and the exposed raw skin dressed with soothing applications.

Patches of eczema ought never to be washed with ordinary soap and water, which has a destructive effect upon the young cuticle of healing patches. Oil, white of egg, oatmeal and tepid water are the most appropriate substances for necessary cleansing, and it is advisable for eczematous persons to use only super-fatty soaps.

The local varieties of eczema are so important that they may be advantageously briefly discussed, and the favourite remedies enumerated.

E. Capitis.—(1) In children: Usually diffuse, pustular, impetiginous, not itchy; pediculi often present as a primary or secondary condition; often of seborrhæic origin; does not cause baldness nor broken hairs. *Treatment:* Removal of crusts by oil, and sometimes subsequent poultice; diluted white precipitate or red oxide ointments (also destroy pediculi), olive oil and lime-water, equal parts, with carbolic acid gr. v ad $\tilde{3}\tilde{j}$; zinc ointment and lanolin, with salicylic acid gr. viiij ad $\tilde{3}\tilde{j}$. Systematic washing, followed by borax ointment gr. xx ad $\tilde{3}\tilde{j}$.

(2) In adults: Usually chronic, dry, squamous, with much itching. *Treatment:* Mild tarry ointments, *e.g.*, oil of

cade 5ss or more, with almond oil 3j, equal parts of soft soap, alcohol, and tar; carbolic lotions, diluted red oxide ointment, ichthyol, with lanolin and vaselin 5 to 20 per cent. (Hutchinson's lotion).

E. Faciei.—(1) Acute: Common, resembles erysipelas, but temperature never much raised, swelling of eyelids, and lax parts marked, but not brawny, nor attended with same feeling of tension; general symptoms much less severe. *Treatment*: Dusting powders and general, as already sketched.

(2) Chronic: (a) In children, associated with pustular *E. capitis*; same treatment suitable.

(β) In adults, often erythematous, with much itching. Oleate of zinc 5j ad 3j and weak carbolic lotions specially useful; about eyebrows and angles of nose often seborrhœic. Treat as above.

E. Labiorum.—Often obstinate; causes painful fissures; must be differentiated from herpes and syphiloderma. *Treatment*: Emollients, glycerine or painting with nitrate of silver or solution of caustic potash.

E. Palpebrarum (Tinea Tarsi).—Common in scrofulous children, and obstinate. *Treatment*: Yellow oxide of mercury ointment (gr. iv ad 3j); dilute citrine ointment, epilation, painting edge of everted lid with solution of caustic potash (gr. x ad 3j), and immediately afterwards with dilute acetic acid.

E. Barbae.—Resembles and may be complicated with sycosis, i.e., folliculitis, but is more superficial; unaccompanied by deep papules and tubercles; spreads to or exists upon other parts; must be carefully differentiated from tinea barbae. *Treatment* must be vigorous and persistent; remove crusts, cut beard close or shave carefully every two or three days, epilate loose hairs; if acute, litharge plaster with olive oil, or ointments of zinc and bismuth; if chronic, white precipitate or ichthyol ointments: specially avoid poulticing.

E. Aurium.—Common, troublesome, often pustular, with crusting. *Treatment*: Remove crusts; syringe often required; mild mercurial ointments, mild tars or carbolic lotion, painting with nitrate of silver or caustic potash solution.

E. Genitulum.—(1) Acute: Common in men, the penis becomes immensely swollen and œdematous, the scrotum excoriated and weeping. *Treatment* as for other acute eczemas.

(2) Chronic: Common in both sexes; itching most distressing, and scratching

causes aggravation of condition; diabetes often present. *Treatment*: Prolonged hip bath, followed by dusting powders or borax lotions; carbolic acid, thymol, or naphthol lotions or ointments, mild mercurials or tars, painting with iodine or nitrate of silver after application of a handkerchief dipped in very warm water; mustard leaf over lumbar spine.

E. Ani.—Very troublesome; simulated by condylomata, especially in children; associated with chronic diarrhœa, worms, varix and fissure. *Treatment*: Careful cleansing of parts with warm water after each motion, regulation of bowels; vermicides; calomel ointment with vaselin; red oxide of mercury ointment; zinc ointment with liquor carbonis detergens; cocaine (5 per cent.) with lanolin, or in suppository; oleates of lead, zinc or bismuth; thymol; painting with iodine or eucatic potash.

E. Intertrigo.—Commonest in groins, inner surfaces of nates, below mammae of obese women as result of contact of surfaces, uncleanness, or sweating. *Treatment*: Lint between surfaces, dusting powders; astrigent lotions, e.g., of sulphate of zinc, borax, acetate of lead; rest.

E. Mammar.—Commonest in nursing primiparae; at first vesicular, then squamous, with painful fissures and much crusting; is very obstinate. A similar condition, known as "Paget's disease," is accompanied by deep infiltration, and is cancerous in nature. *Treatment*: Nipple-guard; remove child altogether, or nurse only on healthy breast; begin with ointments of boracic acid, salicylic acid, or oleates; vigorous washing with spiritus saponis alkalinus; diachylon ointment, or painting with caustics; if completely rebellious, removal with knife.

E. Umbilici.—Resembles syphilitic disease of same part; is tractable. *Treatment*: Zinc ointment.

E. Crurum.—In old people as result of varicosity of veins, and not associated with eczema elsewhere; skin much infiltrated, red, scaly, with indolent ulcers. *Treatment*: Rest, limb elevated, methodical bandaging; if weeping, wash with soft soap and alcohol; diachylon, zinc, bismuth or mild mercurial ointments; lotions of perchloride of mercury, lead and milk, or calamine paint. Martin's bandage useful in some cases of ulcer, applied only during the day, and carefully washed at night. Its action, if beneficial, is obviously so in a few days; if not, had better be discontinued. Iodoform is useful as a local anæsthetic; when pain

is intolerable at night a compound soap pill often valuable.

E. Manuum.—(1) Acute: Common; implicates whole of both hands, with much oedema of dorsum, or is most marked along edges of fingers where deep-seated vesicles abound; very liable to relapse at regular intervals; possibly identical with cheiropompholyx. *Treatment* as for acute eczema elsewhere.

(2) Chronic: Common about palms and knuckles; dry, with fissures; must be diagnosed from psoriasis and syphiloderma. *Treatment*: Stimulant; tars, mercurials, removal of epidermis by Unna's salicylic acid plaster renewed every two or three days, or by soaking in solution of liquor potassæ on rags for days, then dressing with soothing ointments; no washing; india-rubber gloves.

E. Unguium accompanies chronic *E. manuum*. Nails are rough, dull, brittle, and punctate. *Treatment*: Mercurials to roots; arsenic internally.

E. Plantarum.—Resembles *E. palmarum*. J. J. PRINGLE.

ELECTRICITY is used in medical practice for its physical properties, in the investigation of disease, and as a therapeutical agent.

For the purpose of investigating the electrical excitability of nerves and muscles, two batteries are required—viz., a continuous current battery of about twenty to thirty cells, and a faradic or interrupted current battery. The continuous current battery ought to be provided with some arrangement, such as a *dial collector*, by which additional cells may be gradually added to the circuit, and a *commutator*, or mechanical arrangement for reversing the direction of the current. A *galvanometer* is also necessary in order to gauge the strength of the current. It may either be attached to the battery, or independent of it but included in the circuit. It is only by its use that any certainty can be arrived at that the same current strength has been used to produce similar reactions in muscles the condition of which has to be compared. This cannot be decided by the number of cells it is found necessary to employ to produce contractions in corresponding muscles of opposite limbs, because the resistance may be different, as is often the case in a diseased and a healthy limb. No practical means has yet been devised for measuring the interrupted current. We must therefore compare contractions produced by its agency with those pro-

duced in a corresponding muscle in a healthy subject. The operator should always graduate the interrupted current by the strength which will produce contraction of one of his own muscles. The most useful muscles for this purpose are those composing the ball of the thumb. Experience gained from the frequent habit of making electrical examinations will teach an operator what corresponding current ought to produce a contraction in any particular muscle that has to be tested. The strength of current given by each faradic battery also varies, so that when using an unknown battery it is the more essential that an operator should first test its effects on his own muscles.

Every faradic battery should be provided with a *rheostat*—an arrangement for regulating the current either by introducing into, or removing from, the circuit more resistance; or by exposing more or less of the coil of wire to the influence of induction. The best forms of faradic batteries now in use are those in which the inducing current is obtained from one or two galvanic cells. For testing the contractile property of muscle, the primary coil is the better, as the secondary produces a current of higher tension (or, possessing a greater electromotive force), and is therefore more painful; but the secondary current is to be preferred for testing electro-sensibility.

For the use of both batteries, continuous and interrupted, it is necessary to have *rheophores*, or conducting cords from the battery to the patient. At the ends of the rheophores, for the purpose of applying the current to the patient, it is necessary to have instruments of various sizes and shapes called *electrodes*. The limbs to be examined and compared should be placed in the same position. When it is wished to ascertain the condition of the muscles, the skin over them should be moistened with salt and water. Duchenne found that muscles could be more easily excited at certain points, which he called *points d'élection*. These points were afterwards proved to be the positions where the motor nerves entered the muscles, or for deep muscles where the supplying nerve approached nearest the skin, and could therefore be more easily excited. These positions are now called "the motor points," and are depicted in most works on nervous diseases.

For the continuous current a pad should be placed on an indifferent part of the body, and the electrode applied to

the muscle, the condition of which it is required to ascertain, should be made alternately negative and positive by means of a commutator, and the contractions produced compared. Then the contractions produced on the affected limb should be compared with those produced on the healthy side; or, if both limbs be affected, a current registering 2 milliamperes on a galvanometer ought to produce a contraction.

The average resistance offered by the human body, under these circumstances, may be taken to be about 1000 ohms; the resistance of individuals varies considerably, chiefly due to the condition of the skin. More cells will be required with one individual to register 2 milliamperes on a galvanometer than with another. For all practical purposes the resistance of corresponding limbs in the same individual may be taken as equal, although this is not always the case. If a very accurate examination and report be required, it is first necessary to discover the relative resistances of the two limbs. This can be ascertained by the help of a galvanometer. If twelve cells of a battery applied to a limb make a galvanometer register 2 milliamperes, and the same number of cells from the same battery applied to the corresponding limb do not register so much, there is a difference of resistance, the latter limb offering an increased resistance.

In examining for faradic contractility, it is best to remove the pad from the indifferent part of the body, and attach another smaller-surfaced electrode with a handle to the rheophore. If the pad be retained on an indifferent part of the body, an interrupted current is so diffused, and so many muscles are thrown into a state of contraction, that no reliable diagnostic information can be obtained. Therefore it is best to apply one electrode to the trunk of a nerve, and the other to the individual muscles supplied by the branches of that nerve.

When it is desired only to influence the skin in testing the electro-sensibility of a part, one moist electrode should be placed on an indifferent part of the body, and the other, a dry one, such as a metallic brush, applied tightly to the part to be tested, the skin also being allowed to remain dry.

The chief use of electricity in diagnosis is to help in distinguishing cerebral from spinal or peripheral lesions. The current from a constant current battery always flows from the positive to the negative pole, and is called a descending current.

When the polarity of the electrodes is reversed for the purposes of diagnosis, it is assumed that the current flows in the reverse direction, and it is then called an ascending current. The positive pole is called the *anode*, and the negative the *cathode*. In the reactions of healthy muscle to the continuous current a stronger contraction is produced on closing a descending current than on closing an ascending current; or, in other words, a stronger contraction is produced in a muscle when the electrode applied to it is negative than when it is positive—i.e., a cathodal closure contraction is stronger than an anodal closure contraction. This is expressed by the formula $C.C.C. > A.C.C.$

The reverse of this reaction occurs in the "reaction of degeneration," and, as far as electrical diagnosis is concerned, it is the chief point that can be elicited by the use of the continuous current. Erb's definition of the "reaction of degeneration" is:—"A diminution and loss of faradic excitability in both nerves and muscles, whilst the galvanic excitability of the latter remains unimpaired, is sometimes notably increased, and always undergoes definite qualitative modifications."* In some affections the galvanic irritability of nerves and muscles is increased, but the reactions may be qualitatively normal.

The normal polar reactions of nerves occur in the following order:—

- C.C.C. . Cathodal closure contraction.
- A.O.C. . Anodal opening contraction.
- A.C.C. . Anodal closure contraction.
- C.O.C. . Cathodal opening contraction.

In the human subject, where it is impossible to operate on the exposed nerve, the A.C.C. and A.O.C. are about the same in force. The chief practical fact worthy to be noted is that *in health* the C.C.C. exceeds the A.C.C., and the A.O.C. the C.O.C.† In the early stages of some paralyses the galvanic irritability is very often increased. By paralysing the ends of the nerves with curare, the muscle can be made to contract independently of nerve excitation, but the purely muscular contraction is more wavy and prolonged than when the innervation is intact. The interrupted current is of greater use in electro-diagnosis. When interruptions take place more frequently than ten times in a second, a tonic contraction

* "Electro-therapeutics," by Wilhelm Erb, M.D., translated by A. de Wetteville, M.D. (1887.)

† Hughes Bennett.

of healthy muscle is produced, provided a current of sufficient strength be used. When the motor cells at the origin of the nerves, or the nerves themselves anywhere in the course of their distribution, are impaired or destroyed, then the faradic contractility of the muscles they supply is either modified or lost.

Greater use has lately been made of electricity as a therapeutical agent. The known physiological effects of electricity do not explain its beneficial action in many of the diseases in which it is employed. We do not understand what changes take place in a nerve to produce the appreciation of pain, or those which are antecedent to the atrophy of a muscle; nor are we cognizant of the exact molecular change in a nerve which ultimately leads to muscular spasm. We do not understand the mechanism by which a nerve impulse is transmitted along the strands of nerve fibre in the desired direction, or why in certain states of disease we are unable to transmit it, and, in fact, often cannot prevent it taking a course contrary to our will. It is therefore not surprising that we are at present totally at a loss to explain the therapeutical action of electricity.

The knowledge of *catelectrotonus* and *anelectrotonus* naturally leads to the use of the negative pole in the treatment of diseased conditions, which are thought to be due to a decreased nervous excitability, and to that of the positive pole for its calming effect when increased nerve excitation is believed to be present, as in many forms of neuralgia, and often with the most satisfactory results. But *catelectrotonus* and *anelectrotonus*, as far as is known, are only transitory physiological effects of the current, whereas their application to abnormal nervous conditions is often followed by permanent results in the shape of improvement or cure, from which it is inferred that some permanent molecular change had taken place in the nerve.

Other properties are possessed by electricity which may explain many of the phenomena observed to follow its use in the treatment of disease, such as its physical action in the encouragement or retardation of *osmosis*, according to the direction of the current; its chemical properties, on which are dependent what has been called its *catalytic* or *cataphoric* effects, and also electrolysis; and its stimulant, refreshing, and mechanical effects. The latter is a property chiefly exerted by the interrupted current.

Static Electricity.—In early days this variety was the only form used, because it was the only form known. For many years after the discoveries of Galvani and Faraday, static electricity still remained in exclusive possession of the field of electro-therapeutics. The number of accessories required, the expense and cumbersomeness of the machines, and the unpleasant shocks employed in some forms of its administration have prevented the frequent employment of frictional electricity in the treatment of disease, but its use has of late years been revived, especially by Charcot at the Salpêtrière, and no doubt it is the most valuable form of electricity for the treatment of some affections, especially those of an hysterical nature.

Static electricity is administered in several ways. First, by *insulation*, or what may be called a dry electric bath. This is carried out by placing the patient on an insulated couch or chair, and charging him from a frictional electric machine; equilibrium is allowed slowly to re-establish itself through the atmosphere. This treatment is said to produce perspiration, and encourage and increase all the usual secretions of the body. A second method is to take *sparks* from a patient who has been previously charged, or by presenting the part of the patient it is wished to influence to a condenser already charged. A third method is by *shocks*. This is only suited for local application, and consists of discharging a Leyden jar through the part of the patient to be treated—*e.g.*, through the pelvis for amenorrhœa.

Galvanism.—The batteries used for diagnostic purposes may also be employed for the treatment of many affections which can be relieved by galvanism or faradism. In the use of galvanism two methods are followed—one, the “*stable*,” in which both electrodes are kept perfectly stationary, the current passing evenly between the two points; the other, the “*mobile*,” in which one electrode, usually the negative, is moved over the limb or part it is wished to influence. In both cases the skin should be previously moistened with salt water. The best form of electrodes are carbon or metal discs covered with chamois leather. In either method of administering galvanism it is often convenient to have one electrode placed on an indifferent part of the body. The best electrode for this purpose is an oval plate of some pliable metal, such as tin, covered

with a layer of amadou to retain moisture, the whole being enclosed in a loose cover of washleather or flannel, having a waterproof back to protect the patient's clothes. When galvanizing the arms this plate electrode can be slipped beneath the collar to the back of the neck; when the legs are treated it can be applied to the lower part of the dorsal spine and the patient allowed to lie upon it. The greatest chemical and thermal action takes place about the negative electrode, and for this reason it is usually chosen as the movable one.

What is called "central galvanization" consists in applying the negative electrode in succession to the chief nervous centres—viz., to the brain, spinal cord, and sympathetic in the neck—the other electrode being placed on the epigastrium or some other remote part of the body. This method of electrization is generally employed when it is sought to influence the whole nervous system, as in states of great nervous depression, or exhaustion after long illnesses, or in cases of nervous insomnia. Other special affections—such as neuralgias—which are treated by galvanism are often better relieved by applying the positive pole to the painful area. On the other hand, sciatica is more successfully treated by the negative pole, the current used being as strong as the patient can bear.

Faradism.—Faradism does not produce the physiological changes which are so characteristic of the constant current, and is, generally speaking, of less use as a therapeutic agent. It is of greatest service in certain forms of paralysis, as it helps to exercise the muscles, and thus to maintain and promote their nutrition whilst repair may be taking place at the seat of the disease. In some forms of neuralgia, also, it is found more effectual than galvanism. It probably relieves pain by the production of nerve vibrations. When used for the treatment of general conditions of the system, it is either employed in the electric bath, or by what is termed "general faradization," one electrode being placed on an indifferent part of the body, or the feet are placed on a metallic plate, whilst the whole surface of the body is sponged with the other electrode.

Electricity is often of service in those affections which come equally under the care of the physician and the surgeon, such as incontinence of urine, cystitis, and neuralgia after injuries.

W. E. STEVENSON.

ELEPHANTIASIS ARABUM (Barbadoes Leg; Tropical Big Leg) is a chronic hypertrophic disease of the skin and subcutaneous connective tissue, accompanied by cedematous swelling and induration, by pigmentation and papillary outgrowths.

The lower extremities and genitalia are the commonest seats of the disease, but the hands and arms not infrequently suffer also; at first the condition is usually one-sided. Recurrent attacks of erysipelatous inflammation, followed by more or less permanent enlargement of the affected member, first attract attention. During these the adjacent lymphatic glands are enlarged, and the lymphatic vessels show themselves as red lines or knotty cords. At first the skin pits on pressure; afterwards it becomes dense, indurated, and warty from the outgrowth of hypertrophied papillae; dirt accumulates in the folds, dilated surface lymphatics rupture and discharge, maceration and irritation of the mass ensue, causing crusts, fissures, and ulcers. Pain is not usually severe, but the usefulness of the limb becomes impaired from its weight and size. Scrotal and labial elephantiasis may reach huge proportions, and the genital apertures become buried and inaccessible.

Although generally a tropical disease, endemic in the West Indies, South America, West Africa, Egypt, India, and China, sporadic cases occasionally occur in temperate zones. The condition is essentially due to blocking of the lymphatic channels. Tropical elephantiasis is associated with chyluria (*q.v.*) and the presence in the blood and lymphatics of a nematode worm, the *filaria sanguinis hominis* (*q.v.*). In temperate climates recurrent erysipelas or eczema, persistent phlegmasia dolens, or anything causing permanent lymphatic blocking may produce the disease.

Treatment.—In the early inflammatory stages the limb should be kept at perfect rest, cooling lotions used, and general antiphlogistic measures adopted. When permanent enlargement is established, firm bandaging with an elastic bandage from below upwards ought to be maintained, the limb being elevated. Massage in the direction of the lymph stream would probably be of service. Galvanism and the compression or ligation of the main artery to the affected part have been recommended. Finally, free removal of the parts with the knife may be necessary.

J. J. PRINGLE.

EMBOLISM is the blocking of a vessel, usually an artery, by a substance or particle of matter circulating in the blood. Emboli have many sources of origin, which are here named in their relative order of frequency.

(1) Thrombi from the cavities of the heart, either *en bloc* or in fragments. Occasionally a shower of embolic particles are discharged into the circulation owing to a clot having undergone central softening and rupture.

(2) Thrombi (or portions of them) detached from the veins, especially those of the lower extremities and the iliac veins.

(3) Fragments of vegetations from the valves, aneurysmal clots, and atheromatous detritus.

(4) Malignant growths which have perforated the vessels.

(5) Parasites.

(6) Fat molecules, pigment granules, and micro-organisms.

In most cases arterial branches are the seat of impaction. Capillaries may sometimes be blocked, and occasionally the portal vein or its branches.

When an embolus is impacted in an artery, thrombosis occurs above and below, as far as the first large collateral vessel. If the embolus be impacted at the bifurcation of a vessel, the blocking may be incomplete. The clinical differences between the blocking of an artery by thrombosis and by embolism are that the onset of symptoms in the latter is sudden, whereas in the former it is usually slow. Moreover, owing to the sudden obstruction of the circulation in embolism, the immediate and remote results are more severe, because degenerative changes in the tissues commence before the collateral circulation is established.

The organs in which the results of embolism are especially marked are those having arteries with a terminal distribution. When an embolus is impacted in an artery of the lungs, spleen, kidneys, or brain, a wedge-shaped portion of tissue corresponding to its distribution is deprived of blood, and, as the obstructed vessel has no anastomosis, there is no possibility of a collateral circulation being established. The portion of tissue thus deprived of blood loses its functions and undergoes degenerative changes. There is an afflux of blood to the vessels in the immediate neighbourhood, causing a well-marked zone of hyperæmia. Unless the embolus obstruct a large artery, it

is not of much importance if the affected organ have only a single function, but in the brain, where every portion of the cortex is differentiated to some particular function, blocking of a vessel may cause irreparable loss of power.

The term *infarct*, although implying an infiltration of a part, is used indifferently whether the wedge-shaped area become filled with blood or remain permanently anæmic. In the latter event it is called a *primary white infarct*. This is seen especially in embolism of the vessels of the brain and of the arteria centralis retinae. The changes which occur in the tissues deprived of blood are first coagulative necrosis and subsequently fatty degeneration.

Secondary white infarcts arise from the red infarcts by absorption of the pigment.

Red infarcts, often termed *hæmorrhagic*, have an appearance on section like damson cheese; the wedge-shaped area of tissue is so swollen by exudation of blood from the vessels that its base projects from the organ as a rounded prominence. There are two views as to the mode of production of this form of infarct. Cohnheim explains it thus:—After embolism, in the lungs, spleen, or kidneys, the branches of the artery beyond the seat of impaction contract and empty the capillaries and arterioles; the pressure in these vessels then becomes lower than that in the veins, and blood regurgitates; but meanwhile the capillary walls have become altered, and the blood escapes from them into the tissues. As embolism is a frequent complication of those forms of heart disease in which there is a back pressure on the veins (*e.g.*, mitral stenosis), this explanation was generally accepted until Litten showed that the true explanation of the occurrence of *red infarcts* on the surface of certain organs having terminal arteries is that these organs are invested with a capsule, which has a distinct source of blood-supply. When an area is deprived of blood by embolism, he states that his experiments lead him to conclude that these small vessels slowly, by small anastomoses, pour blood into the vessels of the anæmic area, which blood escapes (under arterial pressure) from the vessel into the tissue, until the swelling prevents further entrance.

Changes which occur in Infarcts.—The red infarcts undergo decolorization, from changes in the pigment, becoming first brown, then yellow, finally white; if the

infarct be small, it becomes completely converted into fibrous tissue, leaving a scar. If it be a large infarct, the central portions often undergo softening. They may eventually dry up, and leave a depressed scar, an appearance frequently seen on the surface of the kidney.

Infective emboli occur in pyæmia and ulcerative endocarditis. The particles which form the embolus consist of or contain micrococci; these may lead to a suppurative inflammation of the area of infarction, followed by the formation of metastatic abscesses, especially in the former disease.

Capillary embolism occurs in pyæmia, from the obstruction of capillaries by micrococci; in malaria, by pigment granules; and fat embolism of the pulmonary capillaries has been met with in cases of osteo-myelitis, fracture, contusion, and diabetic coma.

Some of the principal clinical results of embolism may be summarized as follows:—Hemiplegia, aphasia, and hemipopia, from blocking of the middle cerebral artery or its branches; and blindness, from embolism of the arteria centralis retinae.

Occasionally a large clot detached from the right heart, or more frequently from the iliac or femoral veins, blocks the pulmonary artery to such an extent as to give rise to sudden death from asphyxia. Embolism of branches of the pulmonary artery is not uncommon in heart disease, and is followed by *pulmonary apoplexy*.

The coronary arteries or their branches may be the seat of embolism, and sudden death may occur from paralysis of the heart, or it may terminate in degenerative changes of a portion of the myocardium. Embolism of the spleen is not attended with any evident symptoms beyond pain, tenderness, and some swelling of the organ. When branches of the renal artery are blocked by emboli, blood may appear in considerable quantities in the urine.

Embolism of the main artery of a limb, except in old people with degenerated vessels and a feeble circulation, is rarely followed by gangrene, but in young people it frequently gives rise to aneurysm.

F. W. MOTT.

EMETICS are substances which produce vomiting. They do this either by their effect on the stomach, or by acting on the vomiting centre in the medulla oblongata. Emetics are termed local or general according to their mode of action.

To the former class belong large draughts of tepid water, alone or in combination with mustard (3ss) or salt (3j), sulphate of zinc (gr. xxx) or sulphate of copper (gr. v-x), or carbonate of ammonium (gr. xxx).

To the latter group belong apomorphine, ipecacuanha (gr. xxx of the powder or 3j of the vinum ipecac.), and tartar emetic (gr. iij) or 5j of the vinum antimonialis. Apomorphine may be used hypodermically (gr. $\frac{1}{8}$); the others are administered by the mouth. Emesis may also be induced by irritation of the fauces with a feather.

Emetics are employed when it is desirable to empty the stomach of its contents, as in some cases of poisoning and of indigestion, or to promote the expulsion of mucus from the air passages, as in bronchitis or broncho-pneumonia—an effect produced by the mechanical compression of the lungs which occurs in the act of vomiting.

EMMENAGOGUES are agents having the power of producing menstruation.

In the strict sense of the word, there is no such thing as an emmenagogue. The only way in which treatment can produce menstruation is by removing conditions which prevent it. Thus iron, by removing anemia; cod-liver oil, quinine, and other tonics, fresh air, exercise, sea air, and sea-bathing, by improving nutrition, may re-establish suspended menstruation. When, in consequence of cold or shock, menstruation has been arrested, we may promote dilatation of the vessels of the pelvic region, and so favour free circulation through this vascular area, and consequent renewal of healthy function, by warm hip-baths and hot poultices to the lower abdomen. If the patient be married, the effect of the menstrual loss may be obtained by the application of leeches to the cervix uteri; and the relief to pelvic congestion so given will favour natural menstruation at the next period. Hot foot-baths, to which mustard may be added, and the administration of a small quantity of hot dilute alcohol at bedtime, are well-known domestic remedies. Many drugs have been recommended—aloes, apiol, permanganate of potash, black hellebore, oil of savin, and cantharides—but there is none from which any effect on menstruation can be predicted.

G. E. HERMAN.

EMPHYSEMA OF THE LUNGS is a condition in which the infundibular

cavities and alveoli are dilated and the alveolar walls atrophied, the result being that the elasticity of the air vesicles is lost, and they are no longer able either to aerate the blood or to expel the contained air.

The chief *symptom* of emphysema is more or less constant dyspnœa, increased by exertion, and accompanied by a feeling of oppression across the front of the chest. As emphysema almost always occurs as a complication of some other affection, the dyspnœa is not invariably of the same character, but, as a rule, it is marked by a very prolonged expiratory effort, which is usually attended by a certain amount of wheezing. The cough which is present in emphysema associated with bronchitis is peculiar, consisting of a succession of short "hacks" interrupting a greatly prolonged expiratory effort. As many as twenty or thirty such coughs may sometimes be counted with one expiration; the patient then takes a deep breath, and again begins a series as long as the former. This may continue till he is fairly exhausted. Emphysema does not, as a rule, in the early stages affect the general nutrition, but emaciation almost invariably occurs sooner or later, coupled with the distressed and rather anxious look which is common to most cases of prolonged dyspnœa.

Physical Signs.—On inspection, the antero-posterior diameter of the chest is seen to be increased, the sternum is arched with the convexity forwards, and the angle of Ludovici is prominent; the natural curve of the spine in the dorsal region is more marked, the shoulders are rounded, the supra-clavicular fossæ obliterated, and the chest, as a whole, is "barrel-shaped." The heart is displaced downwards, and partly from this cause, and partly from the hypertrophy and dilatation of its right cavities, there is pulsation in the epigastrium.

A line of distended venules is often seen just above the margin of the costal arch, forming the so-called "emphysematous girdle."

When the patient takes a deep inspiration, the chest is raised *en masse*, but there is little or no true expansion, the increase in the thoracic space being effected by the descent of the diaphragm. The vocal fremitus is usually diminished, the percussion note is hyper-resonant, and the normal areas of cardiac and hepatic dulness may be completely obliterated. On auscultation, if the change be general throughout the lungs, the in-

spiratory sound is feeble and the expiratory sound prolonged, and, if bronchitis be present, accompanied by wheezing. Should, however, the margins only of the lungs be affected, the inspiratory sound may be harsh. Fine crackling râles are often audible at the bases posteriorly. The above description applies to a case of emphysema as ordinarily observed in association with chronic bronchitis—"large-lunged emphysema." In another form met with in aged persons the chest is small, the lungs being shrunken instead of enlarged, a change probably due to a process of chronic atrophy complicated by a certain amount of emphysema. This is termed "small-lunged emphysema." In this latter variety it is to be noted that the emphysema is often complicated with pleuritic adhesions, from which in the more common form the lungs are generally free.

Another and completely distinct affection, known as *interlobular emphysema*, is occasionally met with in children, and also in adults after injury to the chest. Strings of bubble-like prominences are seen on the surface of the lung, and correspond in direction with the interlobular septa. They may also occur in groups, giving an appearance of fine froth on the visceral pleura. This condition, when not the result of direct injury, is due to the rupture of air vesicles and escape of air beneath the pleura, or to the entrance of air into the mediastinum from the opening up of the deep cervical fascia, as sometimes happens in the operation of tracheotomy. When once the air has obtained entrance into the mediastinum, it is drawn during inspiration, and forced by violent expiratory efforts, along the sides of the bronchi, and so reaches the surface of the lung.

The *effects* of emphysema upon the heart and other organs are fully described in the article on CHRONIC BRONCHITIS; it will be sufficient therefore, here to state that they include hypertrophy and dilatation of the right ventricle and auricle, followed in the later stages by incompetence of the tricuspid valve, distension of the venous system generally, passive congestion of the kidneys and liver, gastric catarrh, albuminuria and dropsy.

Morbid Anatomy.—On opening the chest the lungs do not collapse, but may be seen completely filling the thoracic space and overlapping the heart. They are of a pale-grey tint, pigmented, and usually free from pleural adhesions. They have a soft downy feel, and pit

upon pressure. The margins generally show the most advanced changes, it being here that the large "bullæ," referred to below, are usually found. On inverting the lung, the base will be seen to form a deep cup, from the distension of its edges. The bases are usually congested and oedematous, scattered areas of collapse being often present. On examination with a hand lens, the dilatation of the alveoli will be well seen, the lung presenting a delicate spongy appearance. Fatty degeneration of the alveolar walls is occasionally found, and is by some writers believed to be the primary change.

Emphysema frequently occurs as a compensatory change when any portion of the lung has undergone contraction from disease; hence it almost invariably accompanies phthisis in the stage of arrest, and may completely mask the signs of the original lesion. In doubtful cases, therefore, the sputa should always be examined for bacilli. The change may affect the neighbouring alveoli only, or, if the contracted area be considerable, may be present throughout a whole lobe. When collapse of the whole of one lung occurs as the result of pleural effusion, or when a large area is destroyed in phthisis, the enlargement of the opposite lung is probably partly a true hypertrophy, and in part due to emphysema. It is certainly accompanied by an increase in functional activity, whereas the condition of emphysema implies a lessening of function.

When simply dilated without rupture, a condition not infrequently met with in children, it is probable that the vesicles may regain their normal size, but in advanced stages the change is permanent.

Etiology.—By some writers it is believed that the condition may arise from a congenital defect in the development of the elastic tissue of the lungs; however this may be, it is certain that the affection sometimes appears in several members of a family, but probably they have then been alike exposed to the exciting causes of the disease.

These are mainly such as give rise to sudden increase in pressure of the air within the lungs. In the act of coughing, strain is put upon the walls of the vesicles, the glottis being partially closed during a violent expiratory effort. If this be frequently repeated, dilatation of the alveoli follows, and may proceed to such an extent that the finer partitions become atrophied and break down, the alveoli coalescing to form spaces, often

of considerable size, which are termed "bullæ." Whooping-cough in early life, and in later life the chronic cough which accompanies bronchitis and phthisis, are the most common causes of the disease. Any act of straining which involves muscular effort while the breath is held, such as laborious work, lifting heavy weights, the act of parturition, and perhaps even of defecation, tends in the same direction. Expiratory dyspnoea, from whatever cause, and especially that of spasmodic asthma, is also liable to set up emphysema. Certain occupations, such as glass-blowing and the playing of wind instruments, conduce directly to it; and in any laborious calling where persons are obliged to undertake great exertion when they are more or less "out of breath," the same change may occur. The longer the patients are exposed to the influences which produce increased pressure of air within the lungs the more widespread does the mischief become.

Treatment.—The chief object of treatment should be to prevent as far as possible any increase of the affection. If it be due to any definite exciting cause, such as playing a wind instrument, the indication is clear; if it complicate chronic bronchitis, the patient must avoid as far as possible anything which may give rise to catarrh of the respiratory passages. Over-exertion of any kind must also be avoided, although active outdoor exercise should be insisted on, but it is of especial importance to restrain patients from allowing themselves to get "out of breath." Rowing, football playing, or any sport entailing occasional excessive exertion should be forbidden, and hill walking must only be undertaken in moderation, and at a reasonably slow pace. The tricycle affords an excellent means of exercise for emphysematous persons. Relief has in some cases been given by means of exhalation into rarefied air. The residual air which the diminished expiratory power is not sufficient to expel is thus drawn out of the vesicles, and for the time relieves their hyper-distension. For a description of the apparatus necessary to carry this treatment out, *see* AIR, RAREFIED, THERAPEUTICS OF.

For further information as to the treatment of emphysema the reader is referred to the article on CHRONIC BRONCHITIS. E. CLIFFORD BEALE.

EMPYEMA.—An empyema is a collection of pus within the pleural cavity. In some cases the fluid is purulent from

the first, but far more frequently the effusion is primarily serous.

Symptoms.—The expression is anxious, and there is often a marked degree of wasting and general pallor. The temperature is high and fluctuating, and of the hectic type. Rigors and sweating are often present, but there may be complete absence of fever when the case first comes under observation. There is usually increased frequency of the pulse and respiration, and, in addition to the above, there are the special symptoms of pleuritic effusion, for which the article on PLEURISY should be consulted. A rise of temperature over the surface of skin covering the dull area has been observed, but this is not always found. Oedema of the affected side of the chest is present in some cases, but it has been also noted when the fluid proved to be serous. The collection of pus may be limited by pleural adhesion to a very small area, a condition often difficult of diagnosis, and particularly so when the empyema is situated between the base of the lung and the diaphragm.

If the fluid be allowed to remain, spontaneous rupture through the chest wall, or "pointing" of the pleural abscess, may occur, generally about the fifth interspace in the nipple line. The contents of an empyema may also burrow through the subcutaneous tissues to distant parts, ultimately either appearing on the surface as a pointing abscess or discharging into some cavity. A neglected empyema, however, more often discharges through the lung than in either of the above-mentioned ways. The chief dangers to be feared in cases of empyema are the occurrence of cerebral abscess, acute tuberculosis, and, after operation or spontaneous rupture, of albuminoid disease.

After the removal of the pus the lung may in recent cases expand to a considerable extent; other changes which aid in obliterating the cavity are the contraction of the affected side of the chest, the displacement of the mediastinum, enlargement of the opposite lung, and the upward movement of the diaphragm. Ultimately the process of closure is completed by the growth of granulation tissue within the empyemal sac.

Diagnosis.—As stated in the article on PLEURISY (*q.v.*), the positive diagnosis of empyema can only be made by means of the exploring syringe, which should always be used whenever the presence of pus is suspected.

In a few very rare instances a general

pulsation, synchronous with that of the heart, has been felt over the whole area of a large empyema, and has led to a mistaken diagnosis of aneurysm. On the withdrawal of a few ounces of fluid, the pulsation may cease altogether, owing to the relief of tension. In rapid and acute effusions the shreds of lymph and leucocytes tend to gravitate to the lower parts of the pleural cavity, and, if the exploring needle be introduced in any of the lower intercostal spaces, a turbid—almost purulent—fluid is withdrawn, and may give rise to the false impression that the whole chest is full of pus. In any case of doubt, therefore, a second exploration should be made at a higher level.

Etiology.—The condition is much more common in children than in adults, but may occur at any age as a sequel of acute pleurisy, especially when the latter affection is a complication of septic inflammation elsewhere, or occurs in the course of the infective fevers, and especially small-pox. In the subjects of malarial poisoning, also, a serous effusion is very apt to become purulent, and an acute tubercular pleurisy may also result in empyema.

Treatment.—If the presence of an empyema be discovered by the use of the aspirator, no harm can be done by withdrawing as much of the pus as will flow through the needle, and in some rare cases in children a cure has been thus effected without further operative interference. If, however, the diagnosis be made by the use of an exploring syringe, it is seldom advisable to proceed to paracentesis, as aspiration is usually followed by a rapid re-accumulation of the fluid. A free incision through an intercostal space, followed by the insertion of a drainage-tube, is then the only effective method of treatment.

The exact site to be chosen for the opening must be determined by the circumstances of the case. It is usually best to select a spot about two interspaces above the lower level of the dull area, as, if the opening be made at the lowest point, a long sinus may remain after the chest has contracted, and there may be great difficulty in getting it to heal, whereas the choice of the higher site ensures the opening being opposite to that part of the cavity which is usually the last to close. The sixth or seventh interspace in the mid-axillary line is, generally speaking, the most convenient region in which to open the pleura.

For the details of the surgical treat-

ment of empyema other works must be consulted; only the general principles can be given here. It is in the first place of the greatest importance to secure free drainage for the pus, and to prevent the access of septic air to the cavity. Washing out the sac with warm aseptic solutions (*e.g.*, corrosive sublimate, 1-2000) is a proceeding often recommended, but not quite free from danger, as in several cases severe shock, and in a few sudden death, has occurred during its performance—results possibly due to the fact that insufficient provision was made for the free exit of the fluid injected. If this be done, and care be taken not to inject the fluid faster than it can escape, the proceeding is probably free from risk. In children, and in adults when the intercostal spaces are narrow, it is generally advisable to remove a portion of a rib at the time of opening the empyema, and, should there be much caseous-looking material or curdy pus within the cavity, or a thick membrane on its walls, it should either be washed out by inserting the nozzle of the irrigator beneath it, or scraped away by means of a sharp spoon guided by the finger. "Perflation," or blowing purified air into the sac, has been recommended with the same object, but is a less efficient measure and not free from risk. The injection with a syringe of an ounce or rather more of iodoform emulsion (iodoform 10 per cent., glycerine 70 per cent., water 20 per cent.), after scraping the interior of the sac, has been found of service in some cases. An aseptic condition of the sac may also be secured by placing the patient in a warm-water bath to which some antiseptic solution such as Condy's fluid has been added, the water flowing in and out with the respiratory movements.

If, in spite of long-continued free drainage, and the occurrence of all possible compensatory changes, such as contraction of the chest, displacement of the mediastinum and diaphragm, and some expansion of the lung, the empyema still remain unhealed, it may be necessary to remove longer pieces of several ribs, or even the greater part of one side of the thorax with the thickened pleura, in order to secure the complete obliteration of the cavity. This latter operation is known as "Estlander's" (thoracoplasty); it is a very severe proceeding, and should only be performed when life is threatened from the weakening effect of prolonged suppuration and the super-venion of albuminoid disease. In one recorded case 54 inches of bone were

thus removed—an average of 6 inches for each rib.

The possibility must always be borne in mind that two or more localized empyemata may exist in the same chest. Hence, if relief to the symptoms be not given by free evacuation of the pus, the chest must be carefully examined to ascertain whether a second collection be present. If any such be found, it must be promptly emptied by the same means. Cases of pyo-pneumothorax not of tubercular origin, or empyema ruptured into the lung, are generally best treated upon the lines here laid down.

In the after-treatment of cases of empyema in which free drainage has been established, attention must be directed toward the maintenance of the general health, which will certainly suffer from the exhausting effect of prolonged suppuration. For this purpose, iron, quinine, and cod-liver oil are the best remedies. Burgundy or port wine may also be allowed. Gentle gymnastic movements of the chest may be useful to promote the re-expansion of the lung and the growth of muscles wasted from disuse, but should not be attempted until at least three weeks after the closure of the wound.

E. CLIFFORD BEALE.

ENDEMIC.—A disease is said to be endemic when it affects a particular locality or district, and results from local conditions there existing. Malarial fever is one of the most characteristic examples of an endemic disease.

ENDOMETRITIS means inflammation of the uterine mucous membrane.

Although this is commonly spoken of as a morbid condition existing by itself, it must be remembered that disease of the mucous membrane is usually accompanied by changes in the muscular tissue beneath, and that disease of the muscular tissue of the uterus is accompanied by change in the mucous membrane. When endometritis is spoken of it is meant that the affection of the mucous membrane is the chief morbid condition present, and not that it is the only one.

Endometritis may affect the cervix or the body of the uterus.

(1) **Cervical endometritis**, leading to the production of the condition variously known as "erosion," or "ulceration," or "granular degeneration" of the cervix, is one of the commonest morbid conditions to which the uterus

is subject. The granular erosion is always accompanied by inflammation of the mucous membrane. Catarrh of the cervix may probably occur alone, but its symptoms are then insignificant. The erosion presents different appearances. The *simple* erosion either appears as a ring around the os uteri or as a patch on its anterior or posterior lip, which has lost its smoothness, and is of a deeper red than the healthy tissue. The *granular* erosion is a patch, similar in situation, which looks to the naked eye like a granulating ulcer. In the *papillary* or cock's-comb erosion there are projecting soft papillary growths. The *cystic* erosion is that in which, beside the granular or papillary condition, hard shot-like lumps, of the size of a hemp-seed or of a pea, but sometimes larger, are felt in the tissue, from which, when cut into, thickened secretion, either glairy or purulent, flows. Sometimes these cysts hang down into the cervical canal. In this condition they have been given the fanciful name of *ovula Nabothi*. These are all different stages of the same morbid condition.

Symptoms.—By the formation of new glands the secreting surface of the cervix is increased, and leucorrhœa results. In chronic cases this is the only symptom. In recent cases there is often vascularity of the whole cervix, which becomes swollen and club-shaped rather than conical, and the canal is dilated. In such, beside leucorrhœa, pain in the back and ovarian regions, menstrual pain, and slightly increased menstrual flow are also present. But the disease is never more than a minor disorder. It is often accompanied by disturbance of the general health, such as loss of appetite, dyspepsia, and nervous symptoms; but there is quite as much reason to think that the condition of health leads to the production of the erosion as that the erosion disturbs the general health. The truth is, that the general condition and that of the cervix react on each other. The disturbance of health is often largely the result of the patient's fears.

Prognosis.—The affection, if of recent date, is curable, but if chronic it is either incurable, or not worth the cost of cure.

Pathology.—Different opinions are held as to the mode of origin of the morbid process, whether it begin in the epithelium or in the connective tissue; but there is no doubt as to the nature of the changes when developed. The affected part, which in health is covered by several

layers of squamous epithelium, now has only a single layer of cylindrical epithelium. There is a formation of gland tissue, the size and number of the newly formed glands varying with the advance of the change. There is also proliferation of the connective tissue between the glands. The intervening processes form the granulations or papillary outgrowths which are seen by the eye. Sometimes the mouths of the glands become closed and their secretion is retained, the result being the formation of the cysts above mentioned.

Etiology.—The chief cause of inflammation of the cervix is injury in parturition. Cold, retroflexion, gonorrhœa, ill-adjusted pessaries, and morbid sexual excitement may also give rise to the condition. Though rare, it is sometimes met with in the virgin.

The *treatment* consists in the administration twice daily of a hot vaginal douche (110°–112° F.) for five or ten minutes at a time. The use, once or twice daily, of plugs of cotton-wool soaked in glycerin, or, preferably, of a glycerin pessary (gelatin gr. xx, glycerin ad 3ij), or, if there be pain and the secretion purulent, a boric acid pessary (as above, with gr. xx of boric acid) is beneficial. Once in from five to seven days the cervix should be cauterized. A Ferguson's speculum having been passed, adherent secretion should be wiped away from the cervix with a mop of absorbent wool in the grasp of a speculum forceps; the cervical canal should then be cleaned with cotton-wool wrapped round a Playfair's probe, and a solution of carbolic acid 7 parts, water 1 part, applied to the eroded vaginal portion with a piece of wool held by the forceps, and to the cervical canal with Playfair's probe. Some of the carbolic acid will flow into the upper part of the vagina, but this is of no consequence; care must, however, be taken to mop it up before withdrawing the speculum, as, if any reach the vulva, it will cause much pain. Before applying the caustic, any cysts that are seen should be punctured and their contents let out. Tonics and laxatives should be prescribed, and alcohol forbidden.

In a recent case cure may be expected in about six weeks. If after two months' treatment the local condition be unaltered, cauterization should be given up. If the mode of cauterization above described seem unproductive of benefit, a zinc-alum point may once only be placed in the cervical canal and left there. If the cervix be lacerated and

everted, and if, after the cervix has been once or twice restored to a healthy condition, relapse take place, the lacerations should be repaired by Emmett's operation, and the cervix restored to its natural shape. If the cervix be much elongated and thickened, amputation of the vaginal portion is the best treatment.

(2) **Endometritis of the Body of the Uterus.**—**Acute endometritis** is of rare occurrence apart from other disease, of which it may be either the cause or consequence.

Endometritis occurs in the course of certain acute diseases—small-pox, enteric fever, typhus, cholera, phosphorus poisoning, and measles. In these diseases the symptoms caused by the endometritis are at the time quite overshadowed by the general condition of which it is one of the results. It may leave behind fungous or purulent endometritis.

Endometritis may be a result of retention and decomposition of ovuline structures. In this case, if there be nothing more than endometritis, there will be simply a copious offensive purulent discharge. The *treatment* consists in the removal of what is retained, and in washing out the uterine cavity with 1 in 2000 corrosive sublimate solution. It may be associated with septicæmia, or with uterine phlebitis, or pyæmia, or peritonitis, in which case it will be of little importance as compared with the other far graver conditions present.

Endometritis may be a result of gonorrhœa. This, although it may protract the disease, does not materially alter the symptoms, unless the Fallopian tubes become involved, in which case the endometritis sinks into relative insignificance, both as regards danger and as a cause of suffering.

Endometritis may result from the decomposition of retained menstrual fluid after most of it has been let out. This is to be prevented by careful attention to antiseptic details.

It is believed that endometritis may arise from chill during menstruation, slight attacks of perimetritis coming on in such circumstances being attributed to endometritis extending along the tube. It may result from sexual excesses. Such cases are marked simply by hæmorrhage and sanious discharge, without physical signs, and get well with rest in bed and avoidance of the cause.

Fungous or hæmorrhagic endometritis occurs in two forms—(1) *chronic hyperplastic* endometritis, in which the

body of the uterus is slightly enlarged and its cavity expanded. The lining membrane is hypertrophied, lying in thick folds, which are soft and easily detached. The structure is normal, except that it is more vascular; the glands may be dilated, and there is a round-celled infiltration. In (2) the *polypoid* form there are distinct circumscribed outgrowths, which may be composed of glandular tissue or of granulation tissue, or chiefly of vessels.

Symptoms and Diagnosis.—The important symptoms are irregular and rather profuse hæmorrhages, and in the intervals a thin rusty or pink discharge. Pain is slight. The disease is important on account of the resulting anæmia. On vaginal examination, nothing abnormal is perceived. On bimanual examination, the uterus is found slightly enlarged. The introduction of the sound produces hæmorrhage and reveals slight elongation of the cavity. With these symptoms and signs, the proper course is to dilate the cervical canal with Hegar's dilators, and explore the uterine cavity with the finger. Then either the thickened, readily detachable mucous membrane or the polypoid growths will be felt.

Ætiology.—Fungous endometritis is often a sequela of labour or abortion, or acute disease. It may occur in the virgin. It is more common near the climacteric, and has been attributed to a morbid influence exerted by diseased ovaries; but our knowledge of its causation is far from definite.

The *treatment* is to scrape away the diseased lining membrane with a blunt curette, and then to cauterize the interior of the uterus with nitric acid or with 1-6 solution of perchloride of iron. This treatment will at least stop the symptoms for some months. Relapse may occur, especially in the hyperplastic form, but cure may eventually be expected.

Chronic purulent endometritis is seen in old women, often in association with closure of the cervical canal. The body of the uterus is dilated and thinned. If there be free exit for the discharge, there is little pain, and the purulent discharge is the chief symptom. If the canal be closed, on opening it pus will escape.

The chief importance of this disease is that it gives rise to a suspicion that cancer is present, and it may be necessary to explore the uterine cavity in order to establish the diagnosis.

Treatment.—If uncomplicated, the purulent discharge can be stopped by maintaining free patency of the cervical canal, and injecting 3j-5ij of a 3ss ad 3j solution of silver nitrate into the uterine cavity. This may be repeated in four to seven days, if necessary.

G. E. HERMAN.

ENEMA.—A fluid injected into the rectum. Clyster is the old name.

The most common use of enemata is to open the bowels. For this purpose simple water or soap and water (Oj-ij) generally suffices, but olive oil (3iv) or castor oil (3j) may be added; in cases of intussusception infants' milk has been advantageously used. Astringent enemata are often employed to check diarrhoea, 2 ounces of starch solution with $\frac{1}{2}$ drachm of laudanum being the most efficacious.

Sometimes it is necessary to feed patients by the bowel. Nutrient enemata are usually made of strong beef-tea (3iij-iv) with brandy and yolk of eggs, or peptonized milk may be substituted for the beef-tea; a nutrient enema should not exceed 6 ounces. It is important to wash out the rectum carefully before each nutrient enema. Enemata of salt and water, or of infusion of quassia, are serviceable against thread-worms; 2 to 4 ounces of fluid may be injected for this purpose. The enema opii is useful in painful affections of the rectum or bladder.

ENURESIS (Incontinence of Urine).—Involuntary micturition either during the night only, or both by day and night, is a not infrequent and sometimes very troublesome affection of childhood. It may exist from birth, but more commonly commences about the third or fourth year, or not till the seventh. When it takes the form of dribbling both by day and night, it may in some measure be due to indolence and indifference, but when nocturnal only, such a causation is very doubtful. The condition is almost equally common in the two sexes.

Setting aside such obvious causes as malformation of the bladder or ureters, and stone in the bladder or kidneys, it has been found to be due to the presence of ascarides, rectal polypi, vulvitis, a contracted orifice of the urethra, spasmodic stricture, phimosis, or adherent prepuce; and in girls, to vascular growths at the orifice of the urethra. Sometimes the urine is too acid or too alkaline, whilst

in certain cases disease elsewhere (e.g., morbus coxæ) has appeared to act as an exciting cause.

Sometimes no cause can be found, and in such cases there are good reasons for regarding the condition as analogous to somnambulism, or even to epilepsy, a further reason for this view being that it is sometimes hereditary, and may occur in families where epilepsy or some neurotic taint is inherited. Some subjects of the affection are of deficient intellect, the condition being very common among idiots; but, on the other hand, it may affect unusually precocious children. It has been said that the incontinence is due to lying in too luxurious a bed, but this can hardly have much effect, as it is very common amongst the children of the poor and in children the subjects of general debility. The child may dream that he is in a proper place for micturition; more probably, however, the dream follows on the act of micturition. Some hold that incontinence occurs only during the deepest sleep; others, that it takes place when there is a tendency to waking. The discharge of urine may take place every night, or several times during the night, or only at intervals of a few days. In recent cases some cause will generally be found, often a gastro-enteritis; subsequently, however, it becomes a habit, and is continued long after the cause has ceased.

The total quantity of urine may be increased, which has given rise to the suggestion that in some cases diabetes may have been present.

The *pathology* of the affection is very obscure; the bladder seems to be unduly excitable, and the contractile power of its muscular coats is in excess. When the incontinence occurs by day as well as by night, it is to be presumed there is, in addition, atony of the sphincter. On the other hand, the centre in the lumbar enlargement may be at fault, as the result of some local or general want of tone in the nervous system. Such a constitutional state, it has been pointed out, is occasionally met with in association with rheumatism. It is highly probable that in some boys the conditions which give rise to nocturnal incontinence are analogous to those which, at a later age, produce seminal emissions, for priapism is occasionally found, and the subjects of it have, it is said, in after-life suffered unduly from nocturnal pollutions or have been addicted to masturbation.

Spontaneous recovery takes place in many instances at the period of second

dentition or at puberty. The complaint is said to be more inveterate in girls than in boys, possibly because in them the causes are not so well understood.

Treatment.—Punishment should never be resorted to unless there be very good reason for suspecting that the act is the result of carelessness, for fear is only likely to make matters worse, and may cause serious impairment of the general health. All sources of local irritation should be removed or treated. Attention should be paid to the diet, and the amount of fluid that the child is allowed should be regulated, none being given for two hours before bedtime. The child should always be made to micturate immediately before getting into bed, and should be awakened and taken out of bed once or twice during the night to pass water, and each time he should be thoroughly aroused. The patient should not be allowed to sleep on the back; to prevent this a blister may be applied over the sacrum, or a brush or some hard substance be tied to the pelvis. It is a good plan to raise the foot of the bed on bricks, so that the pelvis may be lower than the feet; the urine as it collects in the bladder will then gravitate to the fundus and not to the neck, and the reflex act of micturition is less likely to be set up. Sponging the back and loins with cold water and wrapping the feet in cold wet towels have been recommended.

If the urine be too acid, the allowance of meat should be reduced, and bicarbonate of potash or liquor potassæ administered internally; if too alkaline, phosphoric acid should be given, as it is very desirable to keep the urine as nearly neutral and as non-irritating as possible. In recent cases perchloride of iron and nux vomica may be given, whilst in the more chronic cases belladonna usually gives the best results. Small doses of the tincture or extract should be administered at midday and in the evening, the dose being gradually increased until some physiological effects are obtained, when it may be diminished. The drug should be continued for some weeks after apparent cure has resulted. In certain cases, especially when the incontinence is both diurnal and nocturnal, strychnine sometimes answers better. Belladonna increases arterial tension, and acts partly on the vesical centre and partly by paralysing the muscles of the bladder. Ergot, bromide of potassium, benzoic acid, digitalis, borax, and chloral hydrate have also been found of service.

The passage of a sound or the application of a 10-grain solution of nitrate of silver to the urethra once a week has occasionally proved beneficial. It is useless to attempt to occlude the urethra by mechanical means. Galvanism may be tried, the positive pole being applied to the back, and the negative indiscriminately to the perineum, scrotum, and hypogastrium; or a shock from an induced current may be given.

EPIDEMIC is a qualifying term used in medicine to signify that the disease to which it is applied affects, during a limited period or periods, a large proportion of the members of a community, nation, or nations.

Though properly an adjective, it is frequently used as a noun, a practice which has led to much confusion. Though it ought not to be understood as involving any ætiological theory, it is frequently used as an equivalent for "contagious," "infectious," or "communicable," owing to the fact that such diseases have all, with possibly a few unimportant exceptions, been known to occur in an epidemic form. It may be said of every epidemic disease the history of which is well known (with the exception of influenza), that it may be proved to exist always among some community or communities. Thus, Asiatic cholera is never absent from the delta of the Ganges; enteric fever is never absent from Great Britain.

When a disease is constantly present it is termed *endemic*, and the country or region in which it is present is termed an endemic area of that disease, and it is assumed that special demological or climatological conditions exist within this area which favour the development of the disease. It would appear that at irregular intervals these favouring circumstances become intensified within the endemic area, and are also brought into existence beyond its borders; cases of the disease then increase in number, and occur in batches or sequences related in place and time, and there is then said to be an epidemic prevalence of the disease. When the disease prevails in succession in a very large number of countries the term *pandemic* is used: thus, in 1847-48 there was a pandemic prevalence of influenza, and in 1869-73 of small-pox.

The causes which favour each one of the epidemic diseases vary, and will be discussed under the head of each disease,

but it is now almost universally admitted of all the epidemic diseases that the most essential condition is the pre-existence of a case or cases, and that such diseases have a specific origin; further, modern epidemiological and bacteriological observations render it in the highest degree probable, to say the least, that the essential condition is the transference, either directly or mediately, of a *materies morbi* from the sick to the healthy, and that other conditions, social or climatological, operate only by favouring this transference.

Measles, scarlet fever, and small-pox are typical examples of epidemic diseases commonly communicated directly from the sick to the healthy; enteric fever and cholera, of diseases in which the connection between the earlier and the later case is commonly mediate (water, food); but epidemic diseases cannot be classified on this basis, owing to the numerous exceptions in both directions. The origin *de novo* of these diseases can be neither affirmed nor denied, but if it ever occur it must be an extremely rare event.

The degree to which an epidemic disease which has appeared in a community will prevail may be in certain cases to some extent foretold. Certain epidemic diseases, as yellow fever, are checked and finally extinguished by cold weather. In the case of epidemic diseases one attack of which confers complete or partial immunity, the number of susceptible individuals may be known or inferred from the extent of previous epidemics, or, in the case of small-pox, from the proportion of persons efficiently re-vaccinated. In the case of epidemic diseases, such as enteric fever, which are commonly water-borne, the condition of the water-supply and general sanitary state will enable a forecast to be made. The mortality from a disease and the severity of the cases vary remarkably in different epidemics. No explanation of the variation in "type" has ever been afforded, although M. Pasteur's observation of the attenuation of virus (especially in anthrax) may suggest one. It has been supposed that certain epidemic diseases stand in some causal connection with each other. For example, it has been asserted that the epidemic prevalence of cholera is always heralded by an increase of the number of cases of diarrhœa and "bowel complaint," and that a prevalence of whooping-cough is preceded by a prevalence of measles. The grounds upon which the theory of "precursors"

rests, however, appear to be insufficient, the examples quoted in its support being probably merely instances of concurrence.

DAWSON WILLIAMS.

EPILEPSY.—A sudden attack involving loss of consciousness with or without convulsions.

Epilepsy occurs in two forms: (1) *petit mal*—i.e., loss of consciousness without convulsions; (2) *haut mal*, or loss of consciousness with convulsions, which are usually general. Another manifestation of the disease is an *epileptiform seizure*, in which localized convulsions occur without loss of consciousness.

As epileptiform seizures are most frequently associated with cerebral tumours, they are described under BRAIN, TUMOURS OF.

Symptoms.—The attack may begin suddenly with loss of consciousness; or the patient may experience various sensations before the fit, called the *aura*, or *warning*.

The *aura* must be considered as quite as much a part of the fit as the subsequent convulsions. The word "aura" was originally used to denote the feeling which some epileptics describe as that of a current of air passing up the limb. This aura, or warning, although referred to the periphery of the body, is really the expression of some discharge taking place in the area of the cerebral cortex in which this particular part of the periphery is represented, and by means of a definite aura, such as tingling in the great toe or the thumb, we are enabled to localize the particular part of the cortex in which the discharge is taking place. The extent and duration of the aura—i.e., the amount of the fit of which the patient is conscious—is determined by the point of time at which unconsciousness ensues; this varies in different cases, and even for different fits in the same individual. An aura occurs in about one-half of the cases, and its duration varies from a few seconds before consciousness is lost to an hour or even a day.

An aura may take the form of (1) a feeling of malaise, headache, tremors and starting of all the limbs, which may last for a whole day before consciousness is lost.

(2) Unilateral sensations in the face, tongue, arm or leg, either sensory, as tingling, numbness, pain, which may be followed by motor symptoms in the part affected, or the motor symptoms may be primary. The sensory symptoms usually precede the motor, and most often affect

the extremity of the limbs. The patient feels a numbness or tingling in the hand or foot; this runs up the limb, and is followed by a contraction of the fingers or toes (usually flexion), and then by flexion of the elbow or knee; or, after tingling is felt in the face, the corner of the mouth is retracted. The motor symptoms may be felt without the sensory tingling, but it is not common for the latter to follow the motor symptoms. Sometimes the patient feels his head being turned towards the same side as the affected limbs.

(3) Epigastric sensations. The patient experiences curious feelings, such as coldness, burning, numbness, or a feeling of weight, which begins either in the abdomen, often at the epigastrium, or in the left side of the chest, and passes upwards along the left side to the throat or head. The aura follows the course of the pneumogastric nerve, and causes palpitation of the heart, dyspnoea, and a feeling of choking; it is sometimes described as if the intestines were being "wound up."

(4) Psychical, a peculiar dreamy state. Some idea comes into the patient's mind, or there is a sense of something horrible and of great terror.

(5) Vertigo, or a sense of giddiness. The patient feels he is turning round, or objects seem to revolve round him, or both patient and objects appear to revolve at the same time and usually in the same direction; sometimes there is the feeling as of falling down a hole or over a cliff.

(6) Special sense auræ may be (i.) visual, including loss of sight, pain referred to the eyeball, the appearance of bright or coloured lights, or of distinct images of people or views; (ii.) auditory, as noises in the ears, buzzing, humming, ringing of bells, or distinct tunes; (iii.) olfactory; (iv.) gustatory, usually of an unpleasant nature.

In a typical severe epileptic fit the patient, with or without a warning, suddenly loses consciousness, falls down possibly into a fire, or against the furniture, often hurting himself severely, sometimes cutting the head or sustaining severe blows; at the same time he often gives "the epileptic cry"—a wild, unearthly scream or yell, which is probably produced by a sudden expulsion of air through the contracted larynx by the tonic expiratory movement of the thorax. Tonic spasm, either of the muscles of both sides of the body or of one side only, then occurs. In the majority of

cases one side of the body is affected before the other; the head and eyes are turned to one side; the corner of the mouth of the same side is retracted; the fingers are flexed in the interosseal position; the elbow is flexed and the arm adducted. The leg of the same side is also affected, the toes, as a rule, being extended, whilst the knee and hip are flexed; the trunk is often rotated to the side to which the head and eyes turn. The same muscles of the opposite side are subsequently involved, though to a less degree, but if the attack begin on both sides at once, the muscles of both sides will be simultaneously involved. This, however, is not so common, and the writer believes that in the great majority of cases, if the fit be observed at the very onset, one side will be seen to be affected before the other.

The tonic condition lasts only a few seconds, and its exact character is therefore very difficult to analyse with absolute accuracy. It gradually merges into the clonic stage, the initial tonic contractions passing into intermittent clonic spasms. The spasms of the side primarily affected are the first to assume the clonic character. The head and eyes and the corner of the mouth are rapidly jerked towards one side; the fingers are spasmodically flexed; the elbow presents a series of flexions; and the whole leg is drawn up and jerked. The opposite side of the body is then affected by the clonic spasm in a similar way, either synchronously with its fellow or a few seconds later. Both sides then contract simultaneously, and the whole body is thrown into violent clonic contractions, the muscles of the abdomen and trunk being affected as well as those of the limbs and head. In this stage the pupils are widely dilated and do not react to light, and the conjunctiva has lost its reflex. The tongue is usually bitten, from being thrust out between the teeth and caught by the lower jaw in clonic spasm. Urine and occasionally fæces are voided unconsciously, and, very rarely, semen is said to be ejected. The face, which in the tonic state may have been pale or unaltered, becomes intensely cyanotic during the clonic condition; the pulse, perhaps feeble at the commencement of the attacks, becomes rapid and stronger in the clonic stage, but, in the writer's experience, it does not cease altogether as the fit begins, and stoppage of the heart's action cannot, therefore, be considered as the cause of an epileptic fit.

The excursions of the clonic spasm gradually become slower and longer and at last cease, muscular relaxation occurring first on the side primarily affected. The patient now lies in a comatose state, with loud rapid stertorous breathing; the face is intensely cyanotic, but becomes less so as breathing is re-established; the limbs are quite flaccid and paralysed, or they may become slightly rigid; the pupils are widely dilated and insensible to light, and the conjunctival reflex is absent. If the fit began with turning of the eyes to one side, it is frequently observed, immediately *after* all clonic spasm has ceased, that both eyes are turned conjugately to the opposite side (observed by the writer in nine out of eleven fits where it was looked for), so that we have here a deviation due to paralysis of the muscles most involved in the fit. This condition lasts for about three minutes, and then the eyes roll from side to side and the pupils oscillate, alternately contracting and dilating.

The knee-jerk may be absent after a very severe fit, but more often it is excessive, and ankle clonus can be obtained for from three to five minutes after clonic movements have ceased; it is often more marked on the side on which the initial tonic spasm occurred. Gradually the plantar reflex, which is at first absent, and the conjunctival reflex return, the pupils become smaller and react to light, and the patient shows signs of uneasiness and may make some incoherent remark, but more often relapses into sleep, on awaking from which he complains of headache and malaise. Before completely recovering consciousness the patient may perform various automatic acts of which he has afterwards no recollection.

In some cases mental derangement is present directly after the fit, attended with acts of violence; or there may be extreme irritability, lasting for some hours or days. The general mental condition of epileptics is frequently very defective.

Minor Attacks (Petit Mal).—These are slight attacks of loss of consciousness without any convulsion. There may be no aura, or the patient may experience a slight feeling of giddiness or faintness, or a sudden start of the whole body, or some mental idea. He suddenly stops in the midst of a conversation, looks strange, the eyes become fixed or vacant, he drops anything he may have in his hands, becomes flushed or pale in the face, or the colour of the face does not alter at all.

If standing at the time, the patient rarely falls; if sitting, he may merely lean back in his chair. Urine is frequently passed involuntarily. The attack only lasts a few seconds, consciousness then returns, and the patient goes on speaking as if nothing had happened. The reflex action of the pupils and conjunctiva is quite abolished during the attack. Slight twitching of the face is occasionally noticed, but nothing approaching to a convulsion. Immediately after one of these attacks patients are very liable to perform automatic actions, such as beginning to undress themselves, taking things out of a cupboard, or going into shops and making absurd requests.

The *diagnosis* of an epileptic fit, and especially of petit mal, has to be made from attacks of *syncope*. In the latter the loss of consciousness is distinctly associated with weakness of the heart's action; the onset is not so sudden, the attack usually lasts longer, is often brought on by some obvious cause, as a hot room or an unpleasant sight, and is unattended by involuntary micturition. In *auditory vertigo*, or Menière's disease, there is usually deafness to sounds conducted through the bones of the head as well as through the air, also noises in the ears, and frequently vomiting, but rarely loss of consciousness.

Hysterical fits differ in that the patient falls more gradually; screaming occurs while convulsions are taking place; the convulsions are purposive, as fighting and biting other people; the limbs are very rigid; there may be opisthotonos and squinting; the tongue is held between the teeth, but is not bitten; there is absence of involuntary micturition, and the pupils and conjunctiva usually react to stimuli. The duration of these attacks may be half an hour or more, and the patient may recover quite suddenly; whereas, epileptic fits rarely last more than a few minutes, and are, as a rule, followed by sleep or headache. A pinch of snuff is often a useful diagnostic test, producing a reflex sneeze in hysterical cases, but not in epileptics.

Malingering must not be overlooked.

In *convulsions* due to uræmia, albumen is present in the urine, a condition which is not found in ordinary epilepsy.

The *prognosis, as regards life*, is not unfavourable, as patients very rarely die in a fit, but if not carefully watched, the danger to life is very serious from falling into water or fire, or from suffocation in bed or while eating. As regards *cessa-*

tion of the fits, it may be stated that this rarely occurs spontaneously, and that about one-tenth of the cases are not improved by any kind of treatment. The prognosis is the more favourable when the fits begin after the age of twenty, and are inherited, and when there is an aura, and less so when the fits occur very frequently, when the major occur in association with minor fits, and when there are marked mental changes (Gowers).

Pathology.—The pathology of epilepsy has been very much advanced in recent years, mainly owing to the labours of Hughlings-Jackson. The seat of the disease was formerly considered to be in the medulla oblongata, in the "convulsive centre" of that region; it was subsequently thought to be due to a general vaso-motor contraction, producing anæmia of the brain, and so convulsions. Although some convulsive seizures may be due to disease or changes in the medulla, it is now considered most probable that nearly all true attacks of epilepsy have their origin in "discharges" of energy from the cells of the grey matter of the cerebrum, especially those of the cortex, which may be called the seat of convulsions. How the discharge is produced is not quite evident, but it is assumed that the nerve cells of the cortex are charged reservoirs of energy, and that in epilepsy the resisting power to this discharge is diminished. The resistance being overcome, the discharge spreads from the starting-point along the lines of least resistance in the cortex, and, by exciting other cells in the neighbourhood, produces the phenomenon of an epileptic fit. In an attack of petit mal the discharge is limited to the highest centres, and does not usually involve the motor centres.

Etiology.—*Predisposing Causes.*—*Sex.* Both sexes are liable to this disease, but females rather more so than males, the proportion being 6 to 5 (Gowers).

Heredity has a very decided influence in predisposing to epilepsy. Different observers give from 28 to 35 per cent. as the frequency with which some form of nervous disease exists in the family. This is most frequently epilepsy, several members of a family often suffering. Insanity and chorea are also met with.

Age.—The age at which epilepsy is most likely to make its first appearance is important. A great many cases begin in infancy at the teething period, during the first eighteen months. The fits then either persist, or recur after an interval, possibly at the second dentition or at

puberty. The period of second dentition, at seven years, is also a predisposing age, but the time when epilepsy is most prone to occur is the age of puberty, fourteen to sixteen. No age up to seventy is exempt, but it is uncommon for the disease to appear after the age of thirty-nine or forty.

Exciting Causes.—In a great many cases no distinct cause can be made out although the friends frequently assign as a cause some event which may have occurred months previously to the first fit. In 37 per cent. some reliable cause may be found (Gowers), the most frequent being a fright, immediately or a few hours after which the fit may occur. Traumatic causes, especially blows on the head, are not uncommon, the fit occurring immediately or shortly after the blow. *Ascarides* frequently produce epilepsy. Acute specific fevers (especially scarlet fever), asphyxia, pregnancy, and masturbation are by some accredited as causes, but the influence of the last was formerly much overrated; it is more probably the result rather than the cause of the disease. Severe mental anxiety or worry is also an exciting cause.

Treatment.—The drugs which have more effect on epilepsy than any others are the bromides of potassium, sodium, and ammonium. It is best to administer one salt at a time, and not a combination of them, so that, if one lose its effect, another may be tried with advantage. The bromide of potassium is most commonly used, but the ammonium salt certainly seems to produce less depression and less tendency to bromism.

The *time* of administration of the drug and the *dose* are important. If the fits occur at various times, gr. xv-xx should be given three times a day before meals; if the fits only occur at night, or in the early morning, gr. xl-5j should be given at bed-time; while, if the attacks come on in the morning whilst dressing, gr. xl should be taken on awakening, and the patient should stay in bed for an hour after.

With the same daily dose it is well to vary the mode of administration—i.e., to give 5j either in two doses of grs. xxx night and morning, or in three doses of gr. xx. Another plan of administering the drug is to begin with a small dose (e.g., gr. xv.), and to gradually increase it until the fits cease. It is important not to omit the bromide too soon. The dose which has stopped the fits should be persevered with for a whole year, and very gradually diminished for

another year, if no fits occur, when the patient may cease to take the drug. Even then, however, its complete withdrawal may be followed by a return of the attacks.

The induction of BROMISM (*q.v.*), a condition produced by a long use of the drug, in which the patient is very stupid and languid, and ACNE (*q.v.*), are the chief obstacles to prolonged courses of bromine. The former disappears only on leaving off the drug, but the latter can, in most cases, be kept down by the addition of liq. arsenicalis \mathfrak{mij} -v.

When a bromide salt alone fails to check the fits it may be combined with tinct. belladonnæ (gr. v-xv), digitalis, especially if there be any cardiac lesion; extr. cannabis indicæ gr. $\frac{1}{2}$, or liq. morphinæ \mathfrak{m} v and upwards. Iron is said to do harm, but the writer has not found such to be the case, and it is certainly useful in anæmic subjects. Borax (gr. xv-xxx) three times a day has stopped the fits when bromide has failed (Gowers).

Counter-irritation, in the form of a blister, or a seton in the nape of the neck, has a marked effect in stopping the attacks in some cases. If there be a definite aura, beginning in the hand or foot, and treatment by drugs has no effect, it would be quite justifiable to trephine over the centre for the movements of this particular part, and remove, under antiseptic precautions, the part of the motor cortex stimulation of which gives rise to the initial spasm of the fit, as has been done by Horsley; but before having recourse to operative procedure, the patient should be put under a thorough course of iodide of potassium, even if there be no history of syphilis. A blister round the wrist, or a ligature suddenly applied, will often stop a fit beginning in the hand. Epileptics should be careful not to eat indigestible food, and the bowels should be kept well open, as neglect of these two precautions is very liable to bring on a fit. The mind should be well occupied, but not overtaxed.

C. E. BEEVOR.

EPISTAXIS (Bleeding from the Nose) may occur spontaneously or result from injury. When spontaneous, the possibility of the patient being the subject of the hæmorrhagic diathesis should be remembered.

Epistaxis not uncommonly occurs in young people about the age of puberty without any assignable cause, and it is still believed by some to occur vicariously for menstruation. In conditions asso-

ciated with much venous congestion, such as heart disease and cirrhosis of the liver, it is of frequent occurrence; also in diseases of the blood, as scurvy and purpura hæmorrhagica, when it may prove most formidable. Epistaxis is common in the early stages of enteric fever and in diphtheria, and is then sometimes of diagnostic value. It is often met with in whooping-cough, and may aid the diagnosis in a doubtful case.

Treatment.—Cold externally to the nose and forehead, and syringing the nostrils with iced water and tincture of the perchloride of iron, should be the first means tried, and, if they fail, the nares may be plugged. The old operation with Belloc's sound is now seldom performed, india-rubber bags, which are inserted empty and then filled with air or water, being more efficient and their use far less painful. Gallic acid in 10-grain doses, or spirits of turpentine in 15-minim doses, may be administered internally.

ERGOTISM.—Ergot is a fungoid growth which attacks the ear of rye and to a less extent wheat, barley, and oats. Meal prepared from rye so affected gives rise to a train of symptoms known as ergotism.

The *symptoms* at first are of an irritant character and include vomiting, purging, and colic; giddiness, headache, formication and itching of the skin, and sometimes affections of sight or hearing. Hæmaturia and jaundice also occur. There are, however, two chief effects, referable to the nervous and circulatory systems respectively, which persist after these symptoms have ceased. The first consists of severe cramps affecting chiefly the legs, and leading to tonic contraction and fixation of the affected muscles—the spasmodic form of the affection, which sometimes ends in general convulsions and death. The other, the gangrenous form, affects the extremities, the fingers, toes, nose, and ears, the usual sequence of events being coldness, pallor, discoloration, lividity, and gangrene of the part. Gradually a line of demarcation forms, and the necrosed part goes through all the stages of dry gangrene.

Treatment.—The removal of the cause is the first aim of treatment, and, whilst the irritant symptoms last, vomiting should be encouraged or induced. The spasmodic form might be combated by careful massage and the internal use of bromide of potassium or opiates. Gangrene if only threatening is best treated by the continuous current used

as in Raynaud's disease; at a later stage the treatment should be conducted in accordance with the rules of surgery.

ERYSIPELAS is an acute, specific, febrile disease, characterized by a special form of inflammatory skin eruption, which spreads by the lymphatics.

The term is unfortunately applied loosely to many other diseases accompanied by an erythematous blush (simple lymphangitis, various erythemata), and also to certain conditions of phlegmonous and diffuse cellular inflammation which may complicate erysipelas, but are due to a different virus—viz., the microbe of septicæmia.

The essential nature of erysipelas has been satisfactorily established by the researches of Koch and Fehleisen, who have isolated the specific streptococci and reproduced the disease in animals by inoculation. In appearance these streptococci closely resemble the pyogenic micrococci, but they grow and conduct themselves differently in various cultivating media, and their inoculation produces a different train of symptoms.

Much discussion has arisen as to whether the disease ought to be classed as "local" or "general." The point is, in the present state of our knowledge, undebatable, as erysipelas corresponds in most respects with other diseases depending upon the entrance into the economy of a specific micro-organism. As regards point of entrance, it must be considered "local." On the other hand, it corresponds with other "general" diseases in requiring a certain incubation period for the development of its manifestations and in their "general" or constitutional character.

Equally artificial is the distinction formerly recognized between "medical" and "surgical" erysipelas, the latter occurring in connection with traumatism, the former without obvious breach of surface. Trousseau pointed out—and subsequent experience has amply confirmed his observation—that "medical" erysipelas, occurring in the great majority of cases upon the face, has its point of origin in the mucous membranes of the nose, mouth, or eyes, where erosions can be demonstrated, and that it spreads thence to the skin. In the few remaining cases where actual breach of continuity cannot be demonstrated there is strong presumptive evidence of its occurrence.

Symptoms and Course.—During the period of incubation, which varies from

a few hours to three or four days, there is generally enlargement and tenderness of the lymphatic glands corresponding to the region about to be affected. The disease is ushered in either by a rigor or a sense of chilliness, with malaise, nausea, or vomiting, pains in the limbs, and a sudden rise of temperature to 103° or 104° F. Some burning or pricking sensation may attract attention to the skin, or the mucous membrane of the throat, mouth, or nose may be found to be sore, swollen, or congested. Soon, however, the rash spreads to the face.

Wherever the skin is involved it is swollen, infiltrated and pits on pressure; it is glazed, hot and of a vivid red colour, which becomes paler on pressure. The margin of the patch is always raised and well defined, either uniform or tongued "zigzag." It extends rapidly or slowly, its extension being modified by the natural lines of cleavage of the skin; in regions where the skin is tightly stretched or firmly bound down, its minimum is noted—e.g., the chin, occipital region, over Poupart's ligament and over joints. On the contrary, regions where the subcutaneous tissue is lax—e.g., the eyelids and scrotum—become enormously swollen.

As the disease progresses, increased local heat, pain and tension are complained of; fine vesication (often only perceptible with a magnifying glass) occurs over the surface of the patch, which becomes more and more brawny and of a deeper yellowish-red colour. Sometimes large blebs form by the coalescence of vesicles; they may burst and some scabbing ensue, but extensive suppuration is rare. In exceptional cases patches of the disease may show themselves at a distance from the original one, but, as a rule, the extension of the eruption is continuous. The temperature generally reaches its maximum in the first two or three days, and seldom exceeds 104° or 105°, but may reach 107° F.: it persists throughout the disease, with marked morning remissions, till the beginning of recovery, when it suddenly—or, more rarely, gradually—falls, and copious sweats often occur. The pulse, at first full and bounding, tends to become small, weak, frequent, irregular and dichrotic in severe cases. During the febrile period the urine is concentrated, high coloured, loaded with urates and uric acid; albumen is often present in considerable quantity, or even blood and casts. The tongue is at first moist and coated; afterwards it tends to become dry and brown. The bowels are generally

confined, but in severe cases diarrhœa is apt to set in, and must be regarded as a sign of evil omen, accompanied as it frequently is by collapse, hyperpyrexia, jactitation, muttering delirium, and other "typhoid" symptoms.

The duration of erysipelas is quite indefinite, and cannot be predicted in any given case; it usually, however, stops between the fifth and twenty-first day, when the rash, ceasing to spread, fades and subsides at its margin, and thence over the patch. Recrudescences and even distinct relapses are, however, of frequent occurrence. In this way the disease may last for six or eight weeks.

Marked desquamation always ensues, either branny or in large flakes, like those of *exfoliative dermatitis* or *scarlatina*.

When the scalp has been affected temporary baldness results, and in other regions chronic abscesses, situated deeply in the skin, or suppuration of lymphatic glands, may render recovery very tedious. Even without these sequelæ patients often remain a long time in a remarkably debilitated condition. Death rarely occurs, but it may result from high temperature, pneumonia pleurisy, peritonitis, or meningitis, or in cases where the neck is involved from extension to the larynx (*inflammatory œdema glottidis*).

The *prognosis* is grave in very young and very old persons, in those suffering from renal disease, in chronic alcoholics, and in women in the puerperal state.

The *differential diagnosis* is generally easy. From eczema and erythema it is distinguished by the rigors, fever and other constitutional symptoms, the character of the spreading margin, and the uniformity of the lesions. The frequent supervention of erysipelas on a patch of eczema must not be forgotten. In young persons acute necrosis with phlegmon may closely simulate erysipelas. As erysipelas presents certain variations and peculiarities according to its seat, a few words may be said with practical advantage as to its *local forms*.

Erysipelas of the face is the commonest local form; it may start from any catarrhal, erosive or ulcerative condition of the nasal, ocular, buccal or aural mucous membranes, whether primary or secondary to diseases of deeper parts (*e.g.*, necrosis of nasal or maxillary bones, diseases of teeth, otitis media with perforation). Œdematous swelling of the eyelids and consequent disfigurement are very marked, while the lips, nose and ears become thickened hard and brawny;

large vesicles and blebs often form. Extension from the eyelids to the cellular tissue of the orbits produces fixation of the eye-balls, often sloughing, and inflammation or atrophy of the optic nerves from pressure upon them, or, more rarely, thrombosis of the ophthalmic veins.

When the *scalp* is involved, headache is almost always a prominent symptom, with delirium and insomnia. If the temperature remain high, these cerebral symptoms become intensified, tremors, mania and coma often occurring. They are referable to hyperpyrexia, as post-mortem experience demonstrates the extreme rarity of meningitis, cerebral abscess, phlebitis, or other metastatic processes, to which they were formerly considered to be due.

Erysipelas of the genitals in males generally arises from a fistulous opening; the œdema and pain are often considerable, and gangrene of the parts over which the urine trickles is by no means infrequent. In females the vulva is often similarly affected from neglect of ordinary cleanliness.

Erysipelas of the trunk is of traumatic or surgical origin in the great preponderance of cases, but in infants it is apt to be set up round the umbilicus (*E. neonatorum*). Formerly the condition was considered as necessarily fatal, but this is far from being the case, although the prognosis is always grave. The disease spreads just like erysipelas in adults, but it has a special tendency to relapse, and is apt to cause sloughing or to leave a diffuse, doughy condition of the skin very like "œdema neonatorum." If a fatal result ensue, it is generally due to extension to the peritoneum or pleura, to pneumonia or diarrhœa. In young children erysipelas may also start from erosions of the anus or genitals, or from vaccination or circumcision wounds.

Recurrent erysipelas (*pseudo-erysipelas*) is a common and generally misunderstood disorder which, although not identical with true erysipelas, receives no notice elsewhere in this work, and is therefore briefly mentioned here. It occurs at any age, but with special frequency in children and in those who are strumous. In adult life, females appear to be more frequently affected than males. It attacks the face exclusively, especially the nose, upper lip and adjacent part of the cheeks; sometimes the lower lip, chin and forehead are also involved. There is some local rise of temperature, and an erythematous blush, with ill-defined margin and some swelling. No

constitutional symptoms of gravity are present. The attack generally lasts four or five days, occasionally longer. After subsidence of the erythema, the swelling persists, and it increases with every recurrence of the condition, which may take place at frequent intervals and without obvious cause. Finally, the parts, owing to blocking of lymphatics, become hypertrophied and firm to the touch, a physiognomy often described as characteristic of struma being thereby produced. The disease is never infectious or epidemic, and is most rebellious to treatment, which, indeed, seems to have no influence in averting recurrence. It may be mistaken in adults for acne rosacea or urticaria gigantea.

Ætiology and Pathology.—The immediate cause of true erysipelas is a specific streptococcus, but various conditions appear to favour its development or augment its virulence, and these may be considered as predisposing causes. Among them may be mentioned insanitary surroundings—*e.g.*, over-crowding, dirt, defective drainage and deficient ventilation. Recent improvements in sanitary science and its practical applications, and the adoption of various antiseptic precautions in surgical practice, have immensely reduced the frequency and mortality of erysipelas, which was formerly the scourge of hospitals. It still, however, exists, and occurs in small epidemics, which are specially frequent during the prevalence of east winds, or of cold, damp weather. In the presence of an epidemic, persons suffering from renal, cardiac or hepatic disease, or dropsy from whatever cause arising, are particularly liable to be attacked, as are chronic alcoholics, women in the puerperal state, and all those who are poorly fed and clothed.

The erythematous blush so common over œdematous limbs, especially after puncture with Southey's tubes, when unaccompanied by constitutional symptoms and unconnected with the existence of an epidemic, must not be considered as erysipelas: it is a simple lymphangitis.

The period of incubation, accompanied by enlargement of glands and preceding the appearance of the characteristic rash, constitutes a point of resemblance to the acute specific fevers, from which, on the other hand, erysipelas differs in the irregularity of its course and in its marked tendency to recur in persons once attacked. The latter point, however, is one of daily diminishing importance as regards the nosological position of ery-

sipelas, the opinion that "recurrent erysipelas" (pseudo-erysipelas, recurrent lymphangitis) is a separate disease receiving more and more support. Fehleisen even states that the micro-organisms are different.

When true erysipelas is once established it is locally infective, and spreads by the lymphatic spaces and vessels, which are found to be crammed with streptococci in chains, especially at and immediately outside the spreading margin of the disease; the cocci are never found in the blood-vessels. As the skin congestion disappears within a few hours after death, the other microscopical appearances are ill-defined and by no means characteristic. The subcutaneous tissue can generally be observed to be infiltrated with leucocytes, and its meshes are wide from serous infiltration.

Treatment.—The most various opinions prevail as to the efficacy of local measures, but there is no reasonable doubt that general treatment is of much greater importance.

A patient suffering from erysipelas ought to be at once isolated, especially in hospital practice, and the same precautions against the spread of the disease adopted as in the case of the acute specific fevers. The sick-room must be light, airy and cool. Absolute rest must be enjoined. The diet should be nutritious and easily digestible. Solids are to be interdicted; milk, beef-tea, chicken-broth, meat extracts and eggs are specially suitable.

Stimulants may be withheld, as a rule, in mild cases, but should be administered freely if the pulse become feeble or any of the previously described bad symptoms show themselves. During the febrile period brandy or whisky is to be preferred; if these cause sickness or increase thirst, champagne may be substituted. During convalescence, port wine, Burgundy and sound claret are preferable. For headache and insomnia, chloral and the bromides are to be preferred to opium and hyoscyamus. When diarrhoea is a prominent symptom, opium is, however, often the only drug which arrests it.

If the temperature be excessive and "head symptoms" prominent, no remedy is so valuable as the cold bath at 80° F. for fifteen or twenty minutes. This may be repeated at intervals of three or four hours if the temperature rise again to 104°.

At the beginning of an attack a purgative is generally serviceable.

No drug administered internally exerts any specific action upon erysipelas. Ringer recommends the tincture of aconite in the very earliest stage, in doses of $\frac{1}{2}$ to 1 minim every fifteen minutes for an hour or two until the skin is moist and the temperature falls, and at longer intervals afterwards. The treatment, however, is not unattended with danger, and its value is more than dubious. The tincture of the perchloride of iron, administered in large doses of 30 to 60 minims every four hours, is still regarded by many as exerting some specific influence on the disease. A considerable proportion of cases certainly seem to do well on this treatment, and the disagreeable effects which might be expected from such doses are seldom noted; but, on the other hand, in most cases the progress of the disease is in no wise arrested by it, and large doses of sulphate of quinine (gr. v-x every six hours) are certainly equally efficacious, and exert an additional beneficial influence upon temperature. Antipyrin, antifebrin, and other similar drugs may be used with the same object.

The large number and variety of *local applications* recommended perhaps afford the best evidence of their doubtful value. Painting the erysipelatous patch and the skin around it with collodion, solutions of nitrate of silver (gr. xv-3j ad 3j), tincture of iodine, or solutions of perchloride or persulphate of iron, with a view to arresting its extension, is a mode of treatment often adopted, but of very dubious utility. The injection of a 2 or 3 per cent. solution of carbolic acid at various points around the raised margin perhaps merits further trial. The protection from the air afforded by repeated dusting with flour or salicylated starch is certainly as efficacious and affords a pleasant sensation of coolness. Cold lead lotion may sometimes be used with benefit, but if there be much swelling and infiltration it is apt to cause or expedite gangrene; the same remark applies with increased force to the application of poultices. When gangrene appears imminent, minute linear incisions or scarifications seem occasionally to ward it off. J. J. PRINGLE.

ERYTHEMA is a term loosely applied to any inflammatory hyperæmia of the skin which disappears upon pressure. In this sense it may be due to any local irritant, and constitute the first stage of any dermatitis. The eruptions of scarlatina, measles, rôtheln, typhus, enteric fever and dengue are morphologically

erythemata, as are many MEDICINAL RASHES (*q.v.*), also the early rose rash of syphilis and those rashes which occasionally occur at the onset of variola and vaccinia, or in the course of diphtheria, tuberculosis, puerperal fever and septicæmia. A vivid, punctiform eruption (*E. scarlatiniforme*), attended with high temperature, often occurs after injuries or surgical operations, and is followed by desquamation. All the preceding may be classified together as "symptomatic" erythemata.

Idiopathic erythema occurs in two distinct forms—(1) *E. congestivum* (vel hyperæmicum), in which the morbid process is confined to mere congestion of the skin; (2) *E. exudativum*, in which infiltration of the skin is a marked feature.

(1) **Erythema Congestivum.**—(a) *E. roseola* consists in the development of congestive patches of a delicate rose colour, scarcely, if at all, raised above the level of the surrounding skin, varying in size from that of a split pea to a finger-nail, and either diffused over the whole surface of the body or in figured groups. The condition is common in young children in association with digestive derangements, and its onset may be accompanied by pyrexia and constitutional disturbance so considerable as to render its diagnosis from the exanthemata a matter of difficulty, in which case it is advisable to act as if the disease were contagious. Occasionally relapses occur. *Treatment* directed to the digestive disturbances is generally rapidly efficacious.

(β) *Chronic, symmetrical, congestive mottling of the skin* is a condition closely allied to the preceding. It affects young adults, especially females; it is very chronic, and may, in exceptional cases, cause considerable disfigurement. The extensor surfaces of the hands, wrists, arms and legs, sometimes also the cheeks, are mottled with dull bluish maculæ, due to the transudation of hæmoglobin. They do not disappear on pressure, and give the skin a marbled appearance, which is intensified by exposure to cold. No subjective symptoms are complained of. *Treatment* has no influence on the condition, which tends to slow, spontaneous recovery.

(2) **Erythema Exudativum** is a definite and interesting disorder, with two important subdivisions. It may be defined as an acute, or sub-acute, non-contagious, inflammatory disease, characterized by the development of symmetrically distributed, raised, erythematous patches, usually discrete, varying greatly

in form and size, accompanied by slight transudation of hæmoglobin or by copious hæmorrhage into the skin, occasionally terminating as vesicles or blebs, and specially liable to relapse. Constitutional symptoms of a rheumatic type are frequently present, but itching and pain are seldom prominent features.

Nothing more definite can be said of the essential nature of the morbid process than that it is probably a vaso-motor neurosis of central origin. The local changes consist in inflammatory dilatation of the vessels of the papillæ with exudation or hæmorrhage into the papillæ, the rete mucosum and more superficial layers of the skin, proportional in amount to the intensity of the process.

(a) *Erythema multiforme (vel polymorphe)* is common in young adults of either sex, especially in spring and autumn, and is very apt to relapse at the same seasons. Exposure to the sun or to sea air may cause a first attack or determine an attack in a person previously affected; the rheumatic habit decidedly predisposes to its occurrence, and it often appears in the course of acute rheumatism or gonorrhœa, and in connection with various disorders of the female generative organs.

A certain amount of malaise with gastric disturbance and fever may precede by some hours or days, or may usher in the appearance of the eruption, which almost invariably occurs on the backs of the hands and feet. The forearms and legs, the vicinity of painful joints—in rheumatic cases—are usually next involved. The trunk and face, even the mucous membrane of the mouth, throat, nostrils and eyes, are affected in severe cases. The lesions consist of flat or slightly convex papules, sharply defined, deep red or purplish in colour, varying in size from a pin's head to a fourpenny piece, or larger; on pressure, the red tint disappears, but a brownish stain remains. The neighbouring lymphatics and glands often inflame. Such is the commonest form—*E. papulatum*. If the papules coalesce to form larger plateaux, the condition is described as *E. tuberculatum*. Soon the centre of each papule or tubercle becomes sunken and bluish, slight desquamation occurs, and the process tends to recovery, the average duration of each papule being from eight to ten days. Abundant hæmorrhage may occur into the papules, bringing the condition into close affinity with that elsewhere described as *PELIO-SIS RHEUMATICA (q.v.)*.

Frequently, shrinking and desquamation occur in the centre of the papules, which continue to extend at the periphery by a raised margin. They form rings (*E. circinatum*, *E. annulare*), which may wander over the entire body, intersecting each other to form elaborate figures with crescentic edges (*E. gyrratum*). Occasionally new rings develop concentrically round older ones, and the forms thus produced, as well as the varieties of colour due to the different ages of the lesions, explain the designation, *E. iris*, applied to them. The occurrence of vesication is not uncommon, and represents the most aggravated type of the disease, *E. vesiculosum*, in which the inflammatory phenomena are so rapid and severe as to result in the transudation of serum in quantity sufficient to penetrate the rete mucosum and raise the epidermis in the form of small vesicles or even of large blebs. These are invariably surrounded by a bright red areola or raised base, and are intermingled with patches which do not vesicate. (Vesication affecting the periphery of patches of *E. iris* give rise to the condition erroneously termed "herpes" iris.)

If the amount of fluid be small it may be absorbed, and a disc of epidermis separate in the form of a scale from each subsiding vesicle. Even when large blebs are formed (*E. bullosum*), pustulation seldom occurs, but thick, yellow crusts result from their rupture, and excoriated patches are left which invariably heal without scarring.

A severe first attack seldom lasts longer than four weeks, but cases tend to become more severe with each recurrence. When the mucous membranes are affected, the patient's condition is a very pitiable one, and occasionally hæmaturia has been observed. Erythema vesiculosum cannot be separated by hard-and-fast lines from a group of diseases elsewhere considered under the name of *HYDROA (q.v.)*.

Differential Diagnosis.—*E. papulatum* may be mistaken for rûtheln, urticaria, papular eczema, or lichen; *E. iris* for tinea circinata; *E. vesiculosum* for variola, herpes zoster, scabies, or impetigo; *E. bullosum* for pemphigus or hydroa.

Treatment has little influence on the course of the disease. Special attention ought to be paid to the state of the bowels. Salicylic acid and salicylates are useful if rheumatic symptoms predominate; quinine is by some thought to be serviceable in preventing recur-

rences, and iodide of potassium (gr. xxx or more in twenty-four hours), has been found efficacious in arresting the disease. Locally, dusting powders, or lotions containing calamine or acetate of lead, are more generally applicable than ointments. In obstinate cases rest in bed ought to be enjoined.

(β) *Erythema nodosum* is occasionally associated with *E. multiforme* as a further development of *E. tuberculatum*, but generally exists as a distinct disease possessing features of its own sufficiently characteristic to warrant separate description. It chiefly occurs in children and weakly young women, and is often accompanied by symptoms not clinically distinguishable from those of sub-acute rheumatism, including insidious cardiac mischief. Multiple, raised, rosy patches, round or oval in the direction of the limb, from $\frac{1}{2}$ to 3 inches in diameter, suddenly develop along both tibiae, and often along the ulnar side of the forearms. They are exquisitely tender, tense and shining; they rarely vesicate, and although their appearance suggests imminent suppuration, they never suppurate. Finally, they become deep purple, subside to the general level of the skin, and undergo the changes in colour characteristic of bruises. The disease usually lasts two or three weeks, and does not tend to relapse; it may be confounded with bruises and syphilitic nodes.

Treatment consists in absolute rest in bed with protection from pressure, and in the administration of salicylates, quinine and iron, according to circumstances. The heart should be carefully watched. Painting with collodion relieves pain.

J. J. PRINGLE.

ESCHAROTICS are substances which destroy the tissues with which they come into contact; they resemble caustics in their action but are more powerful. The part that is destroyed is gradually separated from the healthy tissues by a zone of inflammation, and is called a slough. The chief escharotics are the actual and electric cautery, sulphuric and nitric acids, potash, lime, acid nitrate of mercury, chromic acid and the chlorides of zinc and antimony.

EXANTHEMA, an eruption. "The exanthemata" is the term used to include all the eruptive fevers. They are scarlet fever, measles, rōtheln, small-pox, chicken-pox, typhus fever, enteric fever, and erysipelas.

EXERCISE, by which in the present connection is to be understood only muscular exercise, has long been generally recognized as a valuable preservative of health; it is also a therapeutic agent of the first importance in certain diseases and cachectic states.

Exercise may be *general*, calling into action the greater number of the limb and trunk muscles; or *special*, being limited to certain muscles or groups of muscles.

General muscular exercise has a remarkable effect upon the principal functions of the body.

Respiration.—The number of respirations and the quantity of air inspired in a given time are increased; the amount of air inspired when walking at a very slow pace (two miles an hour) is doubled as compared with standing; when walking at four miles an hour it is trebled. The amount of oxygen absorbed and of carbonic acid (CO_2) eliminated are also increased; during a day of moderate physical exercise the oxidation of carbon is about 40 per cent. greater than on a day of rest.

Circulation.—The force and frequency of the heart's action are increased during exercise, and the arterial blood pressure rises. After cessation of exercise this rise in pressure continues for a short time, but the rapidity of the heart's action falls below the rate of rest. The normal healthy range is an increase of about twenty beats during and a decrease of ten after moderate exercise.

Skin.—The excretion of water, in the form of sweat, is greatly increased. The quantity so lost, instead of being about half or two-thirds of the amount of urinary water, is equal to and may be even double the total secretion from the kidneys. The loss of chlorides and (fatty) acids is also considerable. As the result of active exercise the total amount of water in the body, and especially of that in the blood, is decreased.

Urine.—The amount of urinary water and chlorides is decreased. The total nitrogenous constituents of the urine (urea, uric acid and creatin) are slightly decreased during the period of exercise and are increased during a succeeding period of rest, the increase during rest being probably slightly greater than the decrease during exercise, so that the eventual result is a small increase in the amount of nitrogenous loss.

Muscular System.—Regular constant exercise causes an increase in the density as well as in the bulk of muscle; there is an

actual storage of nitrogenous tissue, the additional amount of nitrogenous food ingested more than compensating for the loss above mentioned. Excessive exertion leads to muscular exhaustion, diminished irritability and finally to degeneration, so that an over-used muscle decreases in bulk.

Digestive System.—Exercise increases the appetite, especially for fat (rather than starchy foods) and for meat. Digestion is also more rapid, and the circulation through the liver is said to be better. The total weight of faeces is decreased. The amount of water ingested is increased, and a considerable proportion is stored up in the body, partially or wholly restoring that lost during exercise.

Nutrition.—An increased elimination of carbon, probably largely due to oxidation of fats in association with the changes necessary for muscular contraction, and a storage of nitrogen in the albuminous constituents of the muscles are the main results of constant, regular, moderate exercise. The increased elimination of water is only after a time balanced by absorption, and apparently the total amount may thus be permanently diminished.

The effects of general exercise on health will now be considered :—(1) In cases of disease due to (a) want of exercise, (b) excessive exercise, (c) exercise without ventilation; (2) In cases of disease curable or relieved by exercise.

(a) *Deficient exercise*, by lessening oxidation and diminishing the efficiency of the circulation, lowers metabolism; the muscular system wastes, while fat and water increase; the muscles become smaller, more flabby, paler, and the heart shares in these changes, so that subsequent exertion favours dilatation. Deficient exercise produces a lowering of pulmonary nutrition, which favours the onset of tuberculosis; it lessens appetite, enfeebles digestive power and favours chronic constipation.

(b) *Excessive exercise* produces more immediate results. The amount of exercise which ought to be taken cannot be precisely defined; the only rule is to stop when exercise of moderate severity has produced a distinct sense of fatigue. A labourer's daily work is about 300 foot-tons; a walk of 9 miles is an amount of work equal to 150 foot-tons; the amount of work done by a man weighing 11½ stone in walking 10 miles is nearly 190 foot-tons, while the amount done by a man weighing 15½ stone is nearly 260 foot-

tons, though the sense of fatigue in both may be the same.

Exercise may be excessive in amount or velocity; to row a mile in an eight-oared racing boat in seven minutes is an amount of work equal to only 18½ foot-tons, though an untrained man may easily exhaust himself by the effort. A due appreciation of this point is essential if exercise is to be safely used as a therapeutic agent.

Severe exercise produces very laborious respiration with occasional sighing; if still persevered in, hæmoptysis may occur. If exercise be too long continued, the slowing of the heart during rest may be attended by intermittence or replaced by palpitation. Over-exertion when frequently repeated produces cardiac hypertrophy, valvular disease, atheroma of vessels, and may even lead to rupture of the heart. Very great increase (120–140) in the rapidity of the pulse, or a disturbance of the rhythm of the heart, during exercise is an indication that it is excessive in amount or velocity.

The sense of fatigue is localized in some part of the nervous apparatus, and, if resisted, may be replaced by sleeplessness when sleep is desired. Tea favours this insomnia, and alcohol diminishes the excretion of pulmonary carbonic acid, so that both these beverages should be eschewed. The more rapidly work is done the more exhausting is it, and the greater is the strain on the muscular organs (heart and voluntary muscles).

(c) Since the amount of CO₂ expired is greatly increased by exercise, the air of a closed room is rapidly vitiated, and headache, loss of appetite and, in time, impaired general nutrition are produced in persons who take exercise in ill-ventilated workshops or gymnasia.

(2) The use of exercise in *chronic cardiac disease* has been reduced to a system by Professor Oertel. In cases of fatty heart with general obesity, in enlargement of the heart from gout and in chronic mitral disease, especially when the latter is associated with dropsy, renal disturbance, bronchial congestion or catarrh, the treatment is very effectual but should be combined with diminution in the amount of fluid and of fat and carbo-hydrates ingested. The patient is required to walk a certain distance up a path with a gentle rising gradient; the occurrence of dyspnoea on exertion, which may be at first very pronounced, is not considered a contra-indication for the treatment. The distance, and there-

fore also the height, are increased daily as the dyspnoea diminishes. Increased heart action thus caused favours the production or restoration of compensatory hypertrophy; the increased force and rapidity of respiration favours the circulation through the lungs and the emptying of the right side of the heart; and all these causes combine to accelerate the venous circulation.

It is said that the tension of the arterial walls relaxes, so that, though the arterial pressure is higher, the arteries are fuller, and that this only occurs in climbing, not in exercise on the flat.

Regulated exercise is of value in cases of *chronic bronchitis* occurring in obese indolent persons, and operates in the same way as in chronic heart disease. In phthisis in a quiescent state and limited to the apex of one lung, it acts by improving nutrition and favouring full expansion of the lung as well as the process of repair.

In *atonic dyspepsia* general exercise has a tonic effect, increasing appetite and digestive power; in dyspepsia associated with plethora, hepatic tenderness and constipation, it favours the hepatic circulation by unloading the right side of the heart and diminishes the tendency to constipation.

In certain *cachectic conditions* outdoor exercise is a powerful remedy—especially in scrofula, the “tubercular diathesis,” and rickets. It is also of great service in some forms of anæmia, but in chlorosis the amount of exercise taken should be very moderate; indeed, chlorotic patients often recover most rapidly when kept completely at rest for a time.

The exercise of *special groups of muscles* is of use in paralysis or paresis from disease, injury or disuse. (1) It may be voluntary where the patient retains some power over the muscles, and performs movements which bring the muscles into action; these movements may be performed against a certain resistance exercised by the hand of an attendant or by a machine (Ling system). (2) It may be involuntary, the muscles being stimulated by electricity (*see* MASSAGE).

DAWSON WILLIAMS.

EXOPHTHALMIC GOÏTRE
(Graves's Disease; Basedow's Disease).—A group of symptoms chiefly met with in women, of which palpitation, prominence of the eyes and enlargement of the thyroid are the most important, though the two latter cer-

tainly, and possibly the first, are not essential to the disease.

Symptoms.—The onset is usually gradual and insidious, but in a few instances the disease has suddenly appeared after great mental emotion. Palpitation is usually the first symptom noticed. The cardiac phenomena are certainly the most constant and the most important, and of these palpitation breathlessness and throbbing of the vessels in the neck are the chief outward signs; the heart's action is greatly increased in frequency, the pulse being rarely under 90, and often over 120; the cardiac impulse can be perceived over a large area, but there is no true heaving impulse. An anæmic murmur is frequently heard over the base of the heart, and, as the subjects of this disease are not seldom rheumatic, signs of organic disease of the heart will be found in a certain proportion of the cases. The marked pulsation in the carotids is associated with a dilatation readily perceptible, and it is probable that the arteries throughout the body are dilated, a belief which is supported by the frequent existence of epigastric pulsation. Pulsation of the central artery of the retina has been described, but it is by no means constant or even common. A well-marked *tâche cérébrale* is not uncommon.

The enlargement of the thyroid is often preceded or accompanied by a sense of fullness, constriction, or choking in the throat. The swelling is generally more marked on one side than the other, the right being most commonly the larger; the isthmus, also, is usually enlarged. The enlargement, though sometimes considerable, never approaches that seen in ordinary goitre; nor is the hardness so often found in the latter affection ever present. But, though the swelling is never very great or very hard, the trachea may be compressed even to a fatal degree. In many cases, over some part of the thyroid a thrill will be felt; it is often so fine that it can only be recognized by the lightest touch. In these cases, and often when there is no thrill, a loud blowing murmur may be heard over the thyroid on one or both sides.

Exophthalmos, when well marked, may always be known by the fact that, owing partly to the great protrusion of the eyes and partly to the retraction of the upper lid, a rim of sclerotic can be seen above and below the cornea, a condition never met with in health; when present in a high degree, it gives the patient a peculiar and savage aspect.

Sometimes the protrusion is so extreme that one or both eyes may become spontaneously dislocated. An eye to which this has once happened will be very liable to it again; and it is not a little remarkable that in these cases the vision is but rarely impaired. Another and more serious danger from the extreme proptosis is ulceration of the cornea, owing to the inability of the lids to close over the eye. This may result in complete loss of sight. Both eyes are not always protruded to the same degree; the right is the more likely to be the prominent eye, and in a few cases the right alone has been affected, the left being in its natural position. The pupils, if altered, will be slightly dilated.

Gräfe's lid-sign consists in the fact that the upper lid does not follow the downward movement of the eye with the perfect harmony seen in health. If the patient look down slowly it will be noticed that the upper lid, instead of following the movement in the usual way, does so in a hesitating and jerky manner, so that an unusual amount of the sclerotic above the cornea is disclosed during the process. Ultimately the lid comes to occupy its normal relative position to the globe, so that it is essential that the eye should be watched carefully whilst the patient is actually looking down, which should be done slowly, or the sign cannot be observed. It is not necessary that there should be any high degree of proptosis before this sign is present, as it has been found in the early stages of the disease before any protrusion has occurred; and, moreover, it is not present in proptosis from other causes. It is worth noting that cocaine, when dropped into the healthy eye, will produce exophthalmos and the lid-sign, and when used in a case of exophthalmos it intensifies the symptom.

Another sign is the apparent widening of the palpebral aperture, associated with, and probably dependent upon, retraction of the upper lid; it is known as Stellwag's sign, and is not always present; with it there has been noticed a diminished frequency of winking.

Besides these three cardinal phenomena, there are others, some of which are tolerably constant, and which may be of diagnostic value. It is almost the rule for these patients to suffer from profuse perspiration, often accompanied by a sense of heat; the sweating is general over the whole body, the skin being found moist even in those situations where it is habitually dry. This

symptom is sometimes the one of which most complaint is made. Paroxysmal attacks of diarrhoea, without any relation to errors in diet or other known cause, constitute another not uncommon feature. A very fine rhythmical tremor, affecting especially the hands, will be found in a very considerable number of cases; it may be so marked as to prevent the patient from writing, but very often it is so fine as to require careful search before it is recognized, especially as the patient is apt to try to conceal it. In females, amenorrhoea is almost constant, and sometimes the menses have never appeared at all. Attacks of sore throat, accompanied by slight redness of the fauces, are often met with, and some patients are liable to causeless seizures of moderate pyrexia, passing off in the course of a few days without leaving any evidence of their origin.

Patches of leucoderma or vitiligo on the neck, arms, legs or face are sometimes seen, and are due simply to absence of pigmentation; whilst with these, or apart from them, pigmented areas, like patches of chloasma, may be found, and in a few cases the co-existence of Addison's disease has been noticed. Urticaria has also been known to occur. The presence of albumen in the urine has been occasionally observed apart from any kidney disease. Emaciation is usually a prominent feature, and the subjects are generally anæmic, whilst nervousness, irritability, change of temper, loss of appetite and digestive disturbances are amongst the chief premonitory symptoms, and persist after the affection is well established.

In a few instances the disease has run a rapid course, and death has occurred in six weeks, being due presumably to the emaciation and exhaustion. As a general rule the course is very slow, and in a large number of cases more or less complete recovery ultimately occurs. Marked emaciation, profuse sweating and diarrhoea, and uncontrollable vomiting are symptoms which indicate that the case will probably terminate fatally. Epistaxis is amongst the later phenomena, but it is not necessarily of bad augury; the eyes may recede and the thyroid diminish in size before death occurs. In a small percentage of cases the patient becomes temporarily or permanently insane.

Diagnosis.—A well-marked case could hardly be mistaken for any other condition, nor could there be much hesitation when palpitation and a rapid pulse coincided with either exophthalmos or

enlargement of the thyroid. If the cardiac phenomena, sweating, tremors and nervousness be present, a diagnosis of the disease would be justified; but in the absence of any cardiac phenomena it may be doubtful, although, if the view of the pathology of the affection expressed below be correct, it is quite conceivable that the heart might escape.

Pathology.—The exact pathology is still a matter of speculation; the cervical sympathetic so frequently accused of being the cause of the disease has often been found healthy. Vascular lesions were found in one instance in the medulla on a level with the nuclei of the eighth pair of nerves, but it is at least possible that they were the result rather than the cause of the disease. The protrusion of the eyes is associated with an increased development of fat in the back of the orbit, but in all probability it is mainly due to the increased vascularity of this region. The enlargement of the thyroid is due to an increased development of interstitial tissue as a result of long-continued and excessive vascularity. The heart may be dilated, and may show signs of organic disease. The theory which would attribute the symptoms to an affection of the inferior cervical sympathetic ganglion does not fulfil all the conditions as regards the three cardinal phenomena, and may safely be set aside.

In endeavouring to frame a satisfactory idea of the disease as a whole, the sweating, diarrhoea, and fever already referred to must be borne in mind. The presence of a vaso-motor centre in the medulla oblongata is an established fact, and it is probable that in its immediate neighbourhood there is a centre regulating the sweat glands, and there is good reason to believe that there is also close by a centre for regulating the heat of the body. A lesion of the medulla which caused paralysis of these centres would be capable of giving rise to all the phenomena of the disease except those referable to the heart, and, inasmuch as the centre for the pneumogastric nerve is quite close, it is a fair assumption that it too might be paralysed, and the frequency of the heart's action be thus explained. The complications sometimes met with would render this view more probable, as diabetes, glycosuria, ophthalmoplegia externa, and bilateral paralysis of the associated movements of the eyes have all been known to occur as complications, and it is a fact that they may be caused by a lesion of the medulla. This view is further supported

by the fact that, in those cases where the exophthalmos and thyroid enlargement are most marked on the right side, the cardiac phenomena are also well marked, it being well known that the right pneumogastric is the chief, if not the sole, inhibitor of the heart's action. It is probable, therefore, that functional disturbance of that portion of the medulla in which these centres are situated is the actual cause of the disease.

Ætiology.—The disease is much more common in women, but is occasionally met with in men, when it presents the same features. It may appear from the time of puberty up to middle life, but is commonest in young women from seventeen to twenty-five. From the fact that the disease is met with in men, and that it is comparatively rare even in women, it may be inferred that amenorrhoea or other menstrual disturbances are not to be reckoned as causes, but rather as effects of the disease. Fear, mental shock, anxiety and worry are amongst the exciting causes in a large proportion of the cases, whilst inherited neurotic tendencies are also frequently present. In some instances the disease has appeared to run in families. In a certain proportion of cases rheumatism will be found amongst the antecedents.

Treatment.—Quiet and freedom from excitement are essential features in the treatment of this disorder; occasionally it will be necessary to confine the patient to bed. Fresh air and a nourishing diet without stimulants are next in importance. Digitalis alone or in combination with iron, iron by itself, belladonna, iodine, arsenic and bromide of potassium, all have their supporters, and have all seemed to do good; at present it is not possible to give any precise directions for the employment of any one of these drugs in preference to any other, but it is certain that they are used with very different degrees of success in different individuals. The continuous current has in the hands of some appeared to exert a beneficial effect; the poles should be applied behind and a little below the angle of the jaw on each side, or the negative pole to the nape of the neck and the positive pole to the thyroid or eyes. When the proptosis is extreme, ice should be applied to the forehead and to the nape of the neck, and the lids may be stitched together to protect the cornea from ulceration. Ice may also be applied to the thyroid when its enlargement is very great; and, when there is a dangerous pressure on the trachea the

isthmus may be divided, after which the thyroid will probably shrink; but if the symptoms are not relieved, tracheotomy should be performed.

JOHN ABERCROMBIE.

EXPECTORANTS promote the discharge of the secretions from the air passages. They increase the quantity of the sputum, or make its expulsion easier, either by altering its chemical constitution or by increasing the expulsive power.

They may be classified, according to their influence over the circulation, into *stimulant* and *depressant* expectorants. To the former class belong squill, senega, benzoic acid, benzoate of ammonia, the balsams of Tolu and Peru, tar, and the vapour of chlorine, iodine, ammonia, creasote and carbolic acid. In the depressant group are ipecacuanha, antimony, iodide of potassium, and the alkaline chlorides. Carbonate of ammonium, strychnine and belladonna increase the respiratory movements or stimulate the respiratory centre.

EXPECTORATION.—This term is commonly applied both to the act of expectoration and to the products thereby discharged from the air passages.

In health the secretion of the respiratory mucous membrane is removed by the action of its ciliated epithelium, but when the amount of this fluid is increased, ciliary movement is no longer sufficient, cough is excited in a reflex manner and the secretions are expectorated. Cough consists in a sudden forcible expiration, combined with a momentary closure of the glottis, the effect of which is to discharge the contents of the trachea and larynx into the mouth, and to propel the secretion in the bronchi towards the trachea.

The excessive products of the pharyngeal mucous membrane are got rid of by the process of "hawking."

The sputum or matter expectorated may be derived from any part of the respiratory passages, from the pharynx to the pulmonary alveoli. Owing to the wide distribution of mucous glands throughout this tract, the expectoration always contains mucin in varying quantities. The sputum is described as mucous, muco-purulent or purulent according as it is transparent, semi-opaque or resembles the contents of an abscess. Mucous and muco-purulent sputa are generally thick and tenacious, as distinguished from the purulent variety, which is less viscid. At times

mucous expectoration may be thin and watery. Sputum from the larynx and trachea and from the larger and medium sized bronchi is frothy, whereas that derived from the bronchioles and pulmonary vesicles is always more solid, and contains fewer air bubbles.

The secretion of the pharynx is seldom much aerated, and is particularly tough, owing to evaporation being favoured by the continuous and forcible air current to which the pharynx is exposed.

Mucous secretion consists mainly of water with small quantities of mucin and saline matter. In bronchitis and in all conditions where the sputa are purulent, a small amount of albumin escapes from the blood-vessels and is discharged in the expectoration.

Muco-purulent and purulent sputa often present a nummular appearance, which has been regarded by some writers as pathognomonic of the presence of cavities in the lung; but this is a mistake, for the same appearances may be presented by the expectoration of chronic bronchitis without excavation or bronchial dilatation. The presence of carbon in any quantity gives the secretions a grey or blackish colour.

Fibrinous casts of the bronchial tubes are found in the sputum of plastic or croupous bronchitis.

Blood may be expectorated with the sputum in the shape of streaks or clots, or it may be intimately mixed with the secretions. In the latter case the sputum has a rusty, brick-dust, prune-juice or florid colour, according to circumstances which cannot be considered here. Pure blood may be coughed up when hæmorrhage is profuse and sudden. Various adventitious matters may be voided with the expectoration—hydatid cysts, diphtheritic membrane, portions of new growths of the larynx, pulmonary calculi, carbon in different forms, dust of all kinds (iron, siliceous, &c.), vegetable and animal fibres, fragments of necrotic lung tissue, crystalloid products of chemical change and numerous varieties of micro-organisms. Many of these foreign substances can be recognized with the naked eye; others require the use of the microscope for their detection. In certain morbid states of the bronchi (bronchiectasis, putrid bronchitis), in pulmonary gangrene and in certain cases of abscess and excavation of the lung, putrefactive decomposition of the secretions occurs with the formation of volatile fatty acids (butyric, valeri-

anic. &c.), also of leucin, tyrosin, sulphuretted hydrogen and other products, which impart a terribly offensive odour to the sputum and breath.

Microscopical Examination.—Much information may be obtained by examining the sputum like any other liquid—*e.g.*, urine—without any special preparation. A small quantity of the sputum is transferred to an object-glass, and a cover-glass is gently pressed on the specimen so as to spread it out in a thin layer.

FIG. 1.

Curschmann's Spirals of different Form and Size. $\times 90$.

Mucous sputum consists of a transparent amorphous mucin basis, in which a few epithelial cells of various sizes and shapes are generally recognizable. These cells are squamous, spheroidal, columnar, or columnar-ciliated according to the part from which they are derived. When the expectoration is muco-purulent or purulent, pus-corpuscles, granular matter and frequently small oil globules are discovered. Pigmentary granules, mostly

consisting of carbon, are very commonly present in the sputum of persons living in towns or a smoky atmosphere. Fine needles of fatty acids, and crystals of cholesterin, leucin and tyrosin may be detected when putrefactive processes are at work. Blood-corpuscles are met with in various conditions.

Curschmann's Spirals.—The small thick pellets expectorated towards the close of an asthmatic paroxysm are often found to contain spiral threads of mucin arranged like a corkscrew. At times a central thread can be seen within the spiral coil. These objects, which can often be recognized with the naked eye, are believed to represent casts of the bronchioles, and Curschmann considers that they indicate the existence of an exudative bronchiolitis, which, according to his view, is the lesion on which asthma depends. Subsequent investigation has shown that the spirals are sometimes present in cases of simple bronchitis and pneumonia.

Charcot-Leyden Crystals.—Pointed octahedral crystals, insoluble in ether and alcohol, but soluble in acids and alkalis, were found by Leyden in the sputum in cases of asthma, and were believed by him to have a causal relation to the attack. The crystals appear to be analogous to Charcot's crystals, which are seen in the spermatie fluid and elsewhere. They are said to consist of a combination of phosphoric acid with a complex organic base. Charcot-Leyden crystals are not confined to asthmatic sputum, and therefore possess no special diagnostic value.

Lung Tissue.—If the small, opaque, shreddy particles frequently seen in phthisical sputum be teased out with needles in a drop of water, the characteristic curled, branching, elastic fibres can often be detected. At times, where excavation is proceeding rapidly, the elastic tissue presents traces of an alveolar arrangement, but more often scattered individual fibres are observed. A little practice is needed to recognize lung tissue with certainty, as adventitious threads of cotton and other materials are easily mistaken for elastic fibres. Lung tissue may also be discovered by boiling the sputum with an equal volume of a solution of caustic soda (20 grains to the ounce) for a few minutes, and allowing the fluid to stand in a tall conical glass for twenty-four hours, when the fragments of elastic tissue sink to the bottom and can be detected in the sediment. This latter method, recommended by Fenwick, is more suit-

able for general purposes. The discovery of elastic tissue in the expectoration is a certain sign of the existence of destructive disease of the lung, whether ulcerative or gangrenous, but it does not enable us to distinguish the nature of the disease more precisely.

FIG. 2

Lung Tissue. $\times 90$.

Phthisis (tubercular), being by far the commonest of all the destructive pulmonary affections, is usually indicated when elastic fibres are found in the sputum, but at the same time the presence of gangrene or of ulceration depending upon cirrhosis or bronchiectasis cannot be excluded. However, since Ehrlich's researches simplified the detection in the sputum of Koch's tubercle bacillus, a decisive test of the existence of pulmonary tuberculosis has been brought within the reach of every clinical observer.

Small portions of laryngeal new growths are occasionally coughed up, and may be examined in the fresh state, or they may be embedded in celloidin and cut into fine sections in the usual way. The investigation of the expectoration for "cancer cells" seldom yields trustworthy results.

Micro-organisms.—Microbes of various descriptions may be discovered in the sputum—micrococci, diplococci, streptococci, bacilli and different forms of fungi. At present there are only two varieties—the tubercle bacillus and the actinomycetes or ray fungus—which possess undisputed clinical significance.

Tubercle Bacillus.—This microbe may be detected in the following manner.—The sputum is poured into a flat glass dish and examined against a dark background. A small quantity of the thickest and most opaque part is removed with a clean platinum loop or scalpel, and transferred to a freshly cleaned cover-glass; a second

cover-glass is then placed on the first, and the two glasses are gently pressed together so as to spread out the sputum in as thin and even a layer as possible. The cover-slips are then separated and allowed to dry, after which they are picked up with forceps and passed three times through a Bunsen flame to coagulate the albumin. The preparations are then ready for staining.

The following reagents are required to complete the process:—

1. A solution of fuchsin, either (a) Ehrlich's solution—saturated alcoholic solution of fuchsin 11 c.c.; saturated watery solution of aniline oil 100 c.c. (this solution is apt to undergo decomposition, and should be freshly prepared every fortnight); or (b) Ziehl's solution—saturated alcoholic solution of fuchsin 10 c.c.; 5 per cent. watery solution of carbolic acid 100 c.c. (this solution is much more stable, and may be preserved for months).

2. A concentrated watery solution of methylene blue.

3. A solution of nitric acid—commercial nitric acid 1 part, water 2 parts.

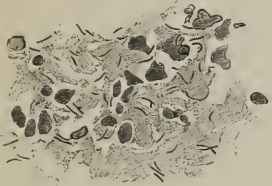

Method of Staining.—The staining fluids must be filtered each time they are used. The cover-glass is now placed with the sputum downwards in a watch-glass or small glass capsule containing the fuchsin solution, and the staining fluid is heated on a sand bath or over a spirit-lamp till it begins to boil. The flame is then removed, and the preparation is allowed to remain about five minutes longer in the hot solution. The cover-slip is next removed with forceps, and immersed for two or three seconds in the nitric acid solution, when the red colour of the fuchsin changes to a brownish grey. The glass is then washed for five or six seconds in a gentle stream of water flowing from a tap, when the red colour reappears. Finally, the preparation is stained in some of the methylene blue solution in the cold for a few minutes, washed again in water, and allowed to dry. The cover-glass is then mounted in Canada balsam dissolved in benzol or xylol, and is ready for examination.

When the staining is satisfactory and the bacilli are numerous, the microbes can be recognized with a magnifying power of from 200 to 300; but when they are scarce, and in all doubtful cases, a sub-stage condenser and a $\frac{1}{2}$ oil immersion lens are indispensable.

The tubercle bacilli by this method of staining appear as delicate rods of a red or crimson colour, the pus corpuscles and

other micro-organisms being stained blue. The staining of the tubercle bacillus may either be uniform or the organism may seem to be indistinctly beaded, an appearance which has been attributed to the presence of spores. Morphological differences of this sort have no diagnostic or prognostic importance.

FIG. 3.

Tubercle Bacilli, Pus Corpuscles, and
Masses of Mucin. $\times 550$.

The discovery of bacilli with these staining reactions in the sputum is a positive proof of tuberculosis of some part of the respiratory tract. Tubercular ulceration of the larynx, pharynx, or trachea may furnish some of the microbes, but the great mass of the bacilli come from the lungs.

When the results of examination are negative, mistakes are very liable to be made, and until the sputum has been repeatedly examined we are not warranted in asserting that tuberculosis is absent. The sputum expelled on waking in the morning is most likely to contain the tubercle bacilli, as it represents the collection of some hours. Moreover, the morning sputum is voided without hawking, and is less likely to consist of pharyngeal secretion.

The number of bacilli found in the sputum is not necessarily a measure of the activity or extent of the disease, it is mainly a question of discharge. When tubercle bacilli are numerous, the existence of pulmonary excavation is almost certain.

The examination of the sputum, so valuable as a method of diagnosis, has, unfortunately, not proved of much service for purposes of prognosis.

Actinomyces.—These organisms have been detected in the sputum in actinomycosis of the lung. The characteristic clubs can easily be recognized with an oil immersion lens without the application of any stain, if the small yellow specks or granules be first sought out with the naked eye or with a low power. For full information on this subject the reader

is referred to the article on ACTINOMYCOSIS.

Micro-organisms in Pneumonia.—The diplococcus pneumoniae and Friedlander's capsule coccus are often found in the sputum of pneumonic patients, the former more frequently than the latter, but their significance is as yet uncertain.

PERCY KIDD.

EXTRA-UTERINE GESTATION means pregnancy elsewhere than in the body of the uterus.

Its causes may be broadly expressed as follows:—Conditions which prevent the ovum from getting to the uterus, but do not prevent the spermatozoa from getting to the ovum. Among these are inflammation of the Fallopian tube, leading to shedding of the ciliated epithelium, which should both aid the movement of the ovum to the uterus and prevent the spermatozoa from travelling along the tube; tumours, or adhesions, partially blocking the tube or rendering it tortuous; emotional disturbances or traumatic influences acting about the time of conception, and perhaps causing some spasmodic contraction of the tube. It frequently occurs after a long period of sterility, being a result of conditions which often altogether prevent normal pregnancy. Extra-uterine gestation is more frequent in multiparae, and occurs with disproportionate frequency in twin pregnancies.

Anatomy.—The most common seat is in the Fallopian tube. Some even maintain that all cases are in the beginning tubal; but the gestation has been found, by dissection in a few cases examined by competent persons, to be in the ovary, or in a tubo-ovarian cyst. Cases of abdominal pregnancy are met with in which no history pointing to previous rupture of a tubal cyst can be obtained, and therefore it is inferred that the pregnancy was primarily abdominal. But the condition of parts is much altered by the pregnancy, and perhaps for this reason no case of abdominal pregnancy has yet been dissected in which it could be demonstrated that previous rupture of the tube had not taken place. The pregnancy may be in that part of the tube which traverses the uterine wall. This is called tubo-uterine or interstitial pregnancy.

Course.—In tubal pregnancy no decidua exists in the tube. As the pregnancy goes on, the chorionic villi become inserted into the mucous membrane of the tube; the growing ovum gradually

expands the tube. Hypertrophy of its muscular fibres takes place analogous to that of the uterus in pregnancy, but less in degree. From the expansion of the tube, the muscular bundles become stretched and separated. Usually between the fifth and thirteenth week the tube ruptures, about the eighth week being the usual period. The ordinary mechanism of rupture is, that slight separation of some chorionic villi takes place, causing hæmorrhage between the ovum and the containing tube, and the distension caused by this effusion of blood bursts the tube.

Several events may now happen. (1) The blood, poured out between the chorion and the enclosing tube, may extensively separate the chorion (as in abortion) before rupture takes place. The separation may be so considerable as to destroy the life of the embryo. In this case, after rupture has taken place, the effused blood, the fœtus and its membranes will be absorbed, and natural cure result. (2) The chorionic villi may not be separated to such an extent as to destroy the vitality of the embryo. In this case the first hæmorrhage, which is commonly slight, may be followed by renewed attacks of hæmorrhage, one of which may at length kill the patient. (3) The rupture may have taken place on the side of the tube which is between the folds of the broad ligament. In this case the blood will be extravasated into the cellular tissue of the broad ligament, and death from hæmorrhage is not so likely to happen. If the fœtus be not killed by the separation of chorionic vessels, it may go on developing under the peritoneum, raising the membrane as it grows; and in this situation it may reach full term. This is called sub-peritoneo-pelvic gestation. (4) Both fœtus and mother may survive even though the rupture take place into the peritoneal cavity, and the pregnancy go on to term. This is called secondary abdominal pregnancy. In such a case the chorionic villi, as they grow and become aggregated together to form the placenta, may attach themselves to almost any part of the peritoneum. The placenta has been found attached to the stomach, small intestine, large intestine, mesentery, omentum, anterior or posterior abdominal wall, uterus, and broad ligament; and it has been seen within the tube, and even within the uterus, while the fœtus was outside. Wherever the placenta is attached, it produces a great

increase in the size and number of the vessels of the part.

While the fœtus is growing outside it, the uterus undergoes a development the same in kind, but less in degree, as that which occurs in uterine pregnancy. It becomes enlarged, its walls thickened, its cavity lengthened, and a decidua thicker and larger than the menstrual decidua is formed within it. At some period in the course of pregnancy—sometimes early, sometimes not until near the end—this decidua is expelled.

When full term is reached, the child dies, and the liquor amnii is usually absorbed. (1) The child may be retained in the abdomen unchanged for an indefinite period, or (2), without detriment to the mother's health, it may become converted into adipocere (rare). (3) The membranes may undergo calcareous degeneration so that the fœtus becomes contained in a stony case, and there may be in time some deposit of calcareous matter in the superficial parts of the fœtus itself. This change is called the formation of a "lithopædion." It is very slow in progress. (4) The fœtus may become shrivelled and mummified. (5) It may suppurate. The soft parts are disintegrated, the bones separated from one another, and at a variable period (on the average about six months, and generally within two years) after the death of the child the abscess bursts. It opens most often into the large intestine; next often externally through the abdominal walls; least often into the bladder or vagina. Through this opening, if the patient survive, first the pus and then the fœtal bones, are gradually eliminated. This is a very tedious process, lasting, if unassisted by art, two or three years, or even longer.

Symptoms, Diagnosis, and Treatment.—From the clinical point of view, we must divide the disease into six stages.

1. Before Rupture.—The reported cases are too few in number to allow us to generalize as to the symptoms before rupture. In almost every case in which the nature of the disease has been shown by operation or by autopsy, rupture had taken place. The diagnosis has never yet been made and confirmed before rupture. A few cases have been cured before rupture by operation, but in them it was not possible to make any closer diagnosis than that there was some disease of the Fallopian tube. Increasing experience may possibly point out criteria by which to distinguish tubal pregnancy from other tube diseases; and

if the diagnosis were made, the proper *treatment* would undoubtedly be to remove the diseased tube by abdominal section.

2. **After Rupture**, but before the foetal heart can be heard, the case may come under notice at various stages: (a) after one or more slight hæmorrhages have occurred, causing symptoms sufficient to attract attention, but not making the patient seriously ill; (b) after profuse internal bleeding has occurred, reducing the patient to a state of collapse; (c) after the patient has recovered from the collapse caused by a severe internal hæmorrhage.

(a) This is commonly the earliest stage at which the condition is diagnosed. There are five indications from which, taken together, the diagnosis may be made with a close approach to certainty. These are (1) a history of the symptoms of early pregnancy—the patient thinks herself pregnant; (2) these symptoms having lasted a month or two, the patient begins to suffer from attacks of severe, paroxysmal abdominal pain; (3) about the same time she begins to have irregular hæmorrhages from the uterus, and with one of these hæmorrhages there may be the passage of a deciduous membrane (a most important sign); (4) there is a swelling behind and on one side of the uterus; (5) there is slight enlargement of the uterus. The severe pains probably depend upon distension of the tube, and the sudden distension of the tube is probably caused by slight hæmorrhage into it. In cases operated on after the diagnosis had been made, the tumour has been found to consist of the dilated tube surrounded by blood clot.

In deciding as to *treatment*, we have to consider the alternatives of expectancy and abdominal section. Galvanism has been recommended, but it practically amounts to expectancy. Puncture by the vagina, and subsequent injection into the sac, or the use of galvanism and cutting into the sac, have also been employed. They bring with them the risk of abdominal section, without the certainty of cure. If the assemblage of symptoms be complete, the best treatment will be abdominal section without delay. If the diagnosis be not clear, but only probable, or possible, the relations and size of the tumour should be defined as exactly as possible, and the case carefully watched to determine if the tumour be increasing in size. If it increase in size, abdominal section should be performed as soon as the fact of increase is certain.

(b) In collapse following profuse hæmorrhage, if the patient be seen before she is so prostrate as to have no chance of recovery, the abdomen should be opened at once, the effused blood let out, the diseased tube removed, and the abdomen washed out and drained.

(c) After the patient has recovered from the collapse caused by a severe hæmorrhage (which is the stage at which most of the hitherto published successful operations for extra-uterine gestation have been performed), it is to be remembered that the hæmorrhage may recur, and that peritonitis may follow, although it seldom does. From these risks the patient is saved by a successful operation. On the other hand, a large hæmorrhage generally, though not always, is accompanied by stoppage of the pregnancy; and if this happen, the patient will recover if she survive the shock of the hæmorrhage. The probability of recovery after operation greatly depends upon the condition of the patient at the time of operating.

The decision as to the course best for the patient is here more difficult than in the before-mentioned circumstances. It must be settled by these considerations:—The less the hæmorrhage, the better the patient's condition, the less likely it is that the pregnancy has come to an end, and the greater is the prospect of recovery from the operation. The greater the hæmorrhage, the more exhausted the patient, the less is the prospect of recovery from operation and the greater the chance that the pregnancy will have come to end. Should symptoms of internal hæmorrhage be followed by those of peritonitis, the abdomen should be opened without delay, the effusion let out and the diseased part removed.

3. **After Symptoms of Rupture have passed off, the Foetal Heart being still audible.**—In this stage of the pregnancy it is not common for very urgent symptoms to arise. The patient may suffer from discomfort caused by the enlargement of the abdomen, or by the foetal movements, or from symptoms of pressure on bladder, bowel, vein, &c., but seldom from any more serious troubles. The diagnosis of pregnancy is easy, for the foetal heart can be heard. The only difficulty is to ascertain that the pregnancy is not uterine. This is best done by careful bimanual examination under an anæsthetic, by which method it is possible to distinguish the uterus from the foetal tumour. It can be felt through the abdominal wall if in front of the sac;

through the rectum if it be behind. Diagnosis may be difficult, for the uterus may be fixed, elongated and spread out in front of the tumour so as to be hardly distinguishable from it. At this stage decision is difficult. On the one hand, the danger to the mother is not greatly increased by waiting till full term, and by operating at term the child is given a prospect of life, and the danger of an operation some time after the child is dead is less than that of an operation in the second half of pregnancy. Operative interference may therefore at this period be postponed, unless demanded by urgent symptoms, and treatment limited to the relief of symptoms by palliative measures. On the other hand, the earlier the pregnancy the less is the danger from hæmorrhage during operation. The experience of the operator must be allowed to weigh in the decision. The earlier the pregnancy, the clearer is the indication for operation; the nearer term, for postponement.

4. At Term.—This is marked by the onset of *spurious labour*. This curious phenomenon is characterized by paroxysmal abdominal pains, which to the patient seem like those of labour, and by a discharge of blood and mucus from the vagina, like the "show" which is an early symptom of normal labour. Dilatation of the cervix has been observed to occur in spurious labour, followed by its contraction when the pains have passed off. This, with other considerations, makes it probable that the spurious labour pains are real uterine contractions. The spurious labour may last from a few hours to two or three weeks. When it has passed off there is a lochial discharge and a secretion of milk from the breasts. The mammary activity may last from a few days to many months or even years.

The ideal *treatment* of extra-uterine pregnancy is the delivery of a living mature child by abdominal section at term. But, up to the present time, four-fifths of the cases so treated have ended in the death of the mother, and the majority of the children have died. Further, a large proportion of extra-uterine children born alive have been deformed. The ideal, therefore, has not yet been reached in practice; and, unless urgent symptoms are present, we shall give our patients the best chance of recovery by letting spurious labour pass off without more than palliative treatment.

5. After Full Term.—At term the child dies, and then, as a rule (not without ex-

ception), the liquor amnii is re-absorbed. The circulation through the placenta then ceases, blood is extravasated into it, and the vascular connections between it and the maternal organism become less and less. The length of time which it takes for the placental circulation on the mother's side to cease varies widely in different cases, so that no rule can yet be laid down.

The *diagnosis* of an extra-uterine gestation after the child is dead will usually be assisted by the history. But if the clinical history be deficient or misleading, the diagnosis may be extremely difficult; indeed, it may be impossible, without an exploratory incision, to distinguish an extra-uterine fœtus from a solid, or partly solid, ovarian or uterine tumour. If there be urgent symptoms, operation is indicated, whatever the nature of the tumour. If the patient be not suffering in health, some guide for treatment will be gained by carefully measuring to see whether the tumour grow or not.

The child may remain for months or years in one of the conditions mentioned above (unchanged, mummified, calcified or converted into adipocere) without causing any disturbance of the mother's health. The placenta becomes gradually absorbed. If this be the course of the case, no treatment is required. If suppuration take place, the commencement of this change will be indicated by hectic fever. The experience of operators prior to the introduction into surgery of antiseptics showed that the best prospect for the patient was to postpone interference as long as possible, so that the operation necessary should be of no greater difficulty or risk than the opening of a large abscess. But this course involves much exhaustion of the patient by hectic fever before the matter is let out, the danger of exhaustion from discharge after operation, and also the danger of the abscess opening into an unfavourable place. The better course is to open the abdomen and remove the child as soon as febrile symptoms begin. It is well to wait for symptoms, because (1) an operation may not be needed at all; (2) the longer we wait, the less will be the vascularity of the placental site, and the more likely will it be that both fœtus and placenta can be removed.

6. After Suppuration and Disintegration of the Child have taken place.—The most favourable place at which the suppurated cyst may burst is the abdominal wall, and next to that the

vagina, because here the opening can most easily be got at. The nature of the abscess, if there be no previous history, will be clear, from the discharge of foetal bones. The treatment is to enlarge the opening as much as is safe, and to remove the foetal bones.

Pregnancy may take place in an imperfectly developed cornu of a bicorned uterus, the connection between the gestation cavity and the cervix uteri being reduced to a mere band of fibro-muscular tissue.

Such cases are difficult to distinguish from tubal gestation even on the post-mortem table. The nature of the case is shown by the insertion of the round ligament, which in tubal gestation is of course internal to the sac; whereas, if the sac be a uterine horn, the round ligament will be attached to its outer aspect. Clinically, as to symptoms, course, and treatment, these cases differ in no essential respect from tubal pregnancy.

G. E. HERMAN.

F

FACIAL NERVE, Paralysis of the (Bell's Paralysis).—Paralysis of the facial or seventh nerve may be produced (1) by lesions at any point in the motor tract—i.e., in the cortex (where the movements of the face are represented in the corona radiata, internal capsule, or crus), at the point of decussation of the facial motor fibres in the pons, or by a lesion in the nucleus of the facial nerve of the opposite side; (2) by disease of the facial nucleus or of the nerve on its way to the facial muscles.

Facial paralysis arising from any of the first-mentioned lesions is considered under HEMIPLEGIA, of which it is a common symptom. The results of the latter class of lesions only are here described.

The facial nerve is liable to be affected in three different places—in the face, from cold, the result of sitting in a draught or riding in a carriage with the window down, or it may be due to an injury, or the pressure of a tumour; in the temporal bone, secondary to disease of the middle ear or due to rheumatic or syphilitic neuritis; and inside the skull, where it may be compressed or destroyed by a tumour, or involved in the lesions resulting from an acute or chronic meningitis.

The nucleus of the facial nerve is liable to be destroyed by tumours in the substance of the pons, and by hæmorrhage or softening.

Symptoms.—The duration of the period of onset of facial paralysis may vary from a few hours to a day or two, or the patient may wake in the morning and find that his face is paralysed. The condition of the face is the same whether the nerve or its nucleus be affected. All the muscles supplied by the nerve are paralysed, and consequently, when the affected side is at rest, the corner of

the mouth is lower and the forehead smoother. When movement is attempted it is seen that the brow cannot be wrinkled or elevated, the eyelids cannot be closed, and, in showing the teeth, the middle line of the upper lip is drawn over to the normal side; whistling and blowing up the cheeks are impossible. At the same time the buccinator is paralysed and the food collects between the cheek and the jaws, and the nostril cannot be opened, as in sniffing. There is no response from the muscles of the affected side to involuntary stimuli, and the patient smiles and laughs on one side only of his face.

It was formerly thought that the soft palate was paralysed in certain cases of facial paralysis, but this is certainly erroneous, as the levator palati is supplied by the accessory nerve to the vagus, and not by the facial (see *Proc. Roy. Soc.*, vol. xlv., a paper by Mr. Horsley and the writer). The only way to test the integrity of the palate muscles is to make the patient phonate, the fact that the soft palate does not when at rest hang straight being no sign of paralysis.

Taste on the same side is lost if the lesion involve the part of the facial nerve between the origin of the large petrosal and the chorda tympani nerves.

The electric reactions are very important, and assist the prognosis of the case. The facial nerve loses its reactions to both faradic and galvanic currents very rapidly; they may have completely disappeared at the end of one or two weeks. The faradic reaction of the muscles corresponds to that of the nerve. The galvanic reaction of the muscles is diminished in the first week; there is then a gradually increasing excitability, which attains its maximum in from three to four weeks, and after that declines. At the same time the contractions of the

muscles are slower and more deliberate, and the serial changes of the reaction of degeneration are observed (*see ELECTRICITY*). The chief point to be noticed is that the muscles react sooner to the positive than to the negative pole.

These changes are due to degeneration taking place in the nerve and muscle, the latter being cut off from its nerve nucleus. As a rule, the reactions of the nerve to both currents and the faradic reaction of the muscles gradually return, reappearing in favourable cases in a few weeks. In cases in which recovery is late the reaction may not reappear until from four to six months, whilst in cases presenting no improvement in motor power the reactions remain permanently absent, and after a time the galvanic reaction of the muscles is also lost.

Recovery of power over the paralysed muscles usually takes place a little before the electric reactions are obtained.

In those cases in which the electric reactions return in a few weeks, the first parts to regain power are the muscles of the forehead and the orbicularis palpebrarum, and it may be several weeks later before the muscles about the mouth improve.

In some cases the facial nerve is so little damaged that there is no change in the electric reactions, or only a diminished reaction to the faradic current. Here, although all the muscles of the face may be completely paralysed, recovery of power is rapid and complete. In old cases, with no improvement, a contraction takes place in the fibrous tissue of the muscles, drawing the mouth towards the paralysed side, and it is only on voluntary movement that one can then tell which is the side affected.

The *diagnosis* of this form of facial paralysis has to be made from that caused by disease of the cortex or internal capsule of the opposite side. In the latter the upper part of the face—*i.e.*, the forehead and eye—is not usually so much affected, though it does not always completely escape; there is no alteration in the electric reactions, and some paralysis of the limbs of the same side is usually present. Another point is that, although the patient cannot voluntarily retract the paralysed angle of the mouth, it is at once thrown into action by emotional stimuli, such as smiling; this is never the case in paralysis of the facial nucleus or nerve.

When the lesion is in the substance of the pons, the sixth nerve of the same side is usually involved, and there is paralysis

of the arm and leg of the opposite side, producing what is called "crossed paralysis." Tumours or meningitis outside the medulla usually cause paralysis of other cranial nerves, especially the auditory. Failing these symptoms, and especially if there be a history of injury or ear disease, the lesion is most probably in the temporal bone.

The *prognosis* in the most common form—*i.e.*, the rheumatic—is favourable as regards recovery according to the way in which the muscles react to the electric currents, but recovery may be delayed for from six to twelve months. The prognosis is good in early syphilitic cases. When the paralysis is due to caries of the petrous bone the prognosis is much more unfavourable, and, unless the lesion be syphilitic, facial paralysis, due to tumours in or outside the medulla, is part of a necessarily fatal disease.

Treatment.—In "rheumatic" cases, hot fomentations should be applied to the face, with glycerin and belladonna liniment. After the inflammatory condition has subsided, blisters should be applied behind the ear and the constant current employed, but the use of the latter is to be avoided in the early stages. The positive pole should be placed behind the ear of the affected side, and the negative passed gently over the muscles, only the weakest current which will produce a contraction being employed. Even should the muscles react to the faradic current, it is best to employ the constant current, as the use of a faradic current of the strength necessary to produce contraction of the muscles is often exceedingly painful. The constant current should be persevered with so long as there is any reaction in the muscles, but when this is lost it is useless to continue electrical treatment, as the case is then incurable; but so long as the muscles react to the constant current, there is a possibility of recovery taking place. Faradization of the opposite healthy muscles in late contracture of the paralysed muscles has been advised, but it is not to be recommended. The muscles should also be gently rubbed, and this should especially be done in cases of late contraction of the paralysed muscles. Disease of the ear should always be looked for, and treated if present.

In cases due to syphilis, iodide of potassium in increasing doses should be given, and electrical treatment employed. Where the disease is due to non-syphilitic tumours little can be done, as such cases

are as a rule beyond the reach of surgical operation.

Double facial paralysis occurs but rarely; it is produced most often by syphilis, diphtheria and meningitis, or by tumours about the pons, and in some cases from cold. The affection does not call for special description. C. E. BEEVOR.

FACIAL SPASM.—By this term is meant a curious clonic contraction of the muscles supplied by the facial nerve, involving either one-half of the face or only the muscles around the eye, and then termed “blepharospasm.”

The spasm is most commonly reflex to some irritation or disease of the fifth nerve of the same side, and may be produced by carious teeth or cold to the face, and it is believed to be also caused occasionally by the presence of intestinal worms. A tender spot can often be found in the course of a branch of the fifth nerve—*e.g.*, the supra-orbital—pressure upon which stops the spasm. The contractions occur at about the rate at which a person in health blinks, but at times they altogether cease. They are often induced by going out into the cold air. In some cases occurring in children and in girls about puberty the cause of their occurrence cannot be discovered, and the movement is allied to what is called histrionic spasm, a condition in which local involuntary twitchings of the face, acquired in childhood, persist during adult life, and are increased by emotional causes.

The *prognosis* is favourable when any source of local irritation capable of removal can be found, but in the other cases it is very difficult to relieve the affection.

The *treatment* consists in removing any source of irritation, such as carious teeth; and if a painful spot over the fifth nerve exist, a blister there will often stop the movement. In some cases the operation of stretching the facial nerve has proved beneficial. Tonics, such as iron and quinine in full doses, and morphine applied locally and by hypodermic injection, are useful. Galvanism without interruption of the current, the positive pole being applied behind the ear and the negative on the face, the strength of the current being gradually increased, sometimes arrests the spasm.

C. E. BEEVOR.

FACIES HIPPOCRATICA—the aspect of the face seen after prolonged wasting disease, or as the result of star-

vation, or before impending death. The original description by Hippocrates is as follows:—“A sharp nose, hollow eyes, collapsed temples; the ears cold and contracted, and their lobes turned out; the skin about the forehead being rough, distended, and parched; the colour of the whole face being green, black, livid or lead coloured.”

FALLOPIAN TUBES, Diseases of.—Like other mucous membranes, that of the Fallopian tubes is subject to **Inflammation**. It may be primary, due to morbid sexual excitement, to alcoholic excess, to chill, especially during menstruation; or to injury, as from the use of irritating intra-uterine injections. It may be infective, as from gonorrhœa, or from the extension of puerperal endometritis; secondary to disease of the uterus, such as endometritis, cancer, fibroids, retroversion or retroflexion; or result from general blood changes, as typhus, scarlatina, cholera, or phosphorus poisoning; or it may be due to venous congestion, as from heart, lung or liver disease. It is sometimes attributed to perimetritis and hæmatocele; but where these diseases occur with tubal disease, the latter is generally, if not always, the primary change. It may be due to new growths in the tube itself, tubercle being the most common.

The affection may not go beyond slight catarrh, manifested by swelling and injection of the mucous membrane and slight enlargement of the tube by increased secretion, appearances which are commonly seen at autopsies. Inflammation of the tube being a frequent cause of peri-oophoritis and perimetritis, is consequently often found in association with adhesions, especially around its abdominal end. Catarrh of the tube is not only common on the post-mortem table, but is probably as common during life, ending most frequently in recovery. When chronic, it leads to destruction of the ciliated epithelium of the tube, and so to sterility or extra-uterine gestation.

When the abdominal end of the tube has become occluded, its secretion is retained; the fluid may be merely serous or mucous, the condition being then termed **Hydrosalpinx**, or hydrops tubæ. Tubes so distended may reach such a size as to cause them to be mistaken for ovarian cysts; they have been found containing more than a gallon of fluid, but such a condition is rare. The usual appearance is that of sausage or club-shaped swellings, constricted at two

or three points, 2 to 4 inches in length and 1 to 2 inches in diameter. When small, the distension affects only the outer two-thirds or thereabouts of the tube. The disease is often bilateral. The enlarged tubes usually sink backwards into the recto-uterine pouch. After fluid has accumulated in the tube in consequence of closure of its openings, it is possible for the uterine opening to again become permeable, and thus a sudden discharge of watery fluid, which has come from the tube, may be noticed by the patient. This has been called *hydrops tubæ profluens*. It is rare, and probably most of the cases described under this name by old authors were misinterpreted; but there is no doubt that such cases do occur. The fluid may also be discharged into the peritoneal cavity either by rupture or by re-establishment of its abdominal opening, and, if the contents are simply serous, the fluid may be absorbed and the patient get well.

The tube may contain pus. This is called *Pyosalpinx*. The pus may be recent and thin, or it may be old, thick and inspissated. It is often accompanied by much thickening of the wall of the tube, and by adhesions of the tube to neighbouring parts. The mucous membrane of the tube may be ulcerated, and the ulceration may perforate the tube, letting out the pus into the peritoneal cavity; or the wall of the tube may be in places thinned, and may burst at a thinned spot. The pus may also escape through the abdominal end of the tube into the peritoneum. In whatever way the pus gets into the abdominal cavity, the result is acute and, if not treated, rapidly fatal, peritonitis. The pus may also be discharged by perforation into other parts, as the rectum, the vagina, or externally. It may also, like serous accumulations, escape through the natural opening into the uterus.

The tube may contain blood. This is called *Hæmatosalpinx*. Bleeding from the mucous membrane of the tube is not uncommon; indeed, there is reason to think that it is an important part of normal menstruation, and that slight hæmorrhages, not of sufficient extent to cause marked symptoms, occur in many pathological conditions. It is only when the tube is closed and the blood retained that it becomes a source of trouble. It may occur as a result of menstrual retention (see *AMENORRHOEA*). It is believed that even when there is not absolute closure of the genital canal,

but only slight and temporary hindrance to the escape of menstrual or other blood from the uterus, some of it may regurgitate into the Fallopian tubes. As a result of extra-uterine gestation, it is one of the most important conditions of the tube.

Signs and Symptoms.—During life, dilatation of the Fallopian tube can be made out by bimanual examination, but it cannot be decided whether the tube contains watery fluid, pus, or blood. Stretching of the tube causes pain, and in each of these conditions there is, as a rule, persistent pelvic pain, worse at the menstrual period, and aggravated by sexual intercourse. Menstruation is usually too copious, and the flow may be too frequent; but this symptom is not constant enough to be relied upon.

On physical examination, a tender lump is felt on one or both sides of, and behind, the uterus; and, on careful bimanual examination, the swelling is found to taper off into a cord which runs to the upper angle of the uterus. This sign applies equally to small ovarian cysts; but they are, as a rule, neither painful nor tender. But when a small ovarian cyst has suppurated, the symptoms and signs are practically indistinguishable from those caused by a dilated Fallopian tube, except that they are less influenced by treatment. If, as often happens, the pelvic organs are matted together by adhesions, it may be impossible to ascertain with certainty the relations of the swelling. In some cases, after masses of tissue enclosing suppurating cavities have been removed from the body by operation, the parts are so matted together by adhesions, and so torn in the process of removal, that it is impossible, even on dissection, to say whether the cavities are dilated tubes or not; and, in such, the only diagnosis that can be made is that there is disease of the uterine appendages.

Treatment.—The majority of cases of inflammation of the tubes will get well with rest in bed, light diet without alcohol, laxatives, counter-irritation to the skin of the abdomen, and avoidance of intra-uterine treatment. Their course is chronic, often lasting many weeks, and they are prone to relapse. If this treatment, though persevered in, fail to do good, and the patient's suffering be such as to prevent her from performing her domestic and social duties, the diseased parts may be removed by abdominal section. If, in a patient suffering from chronic disease of the uterine appendages, acute peritonitis

come on, abdominal section should be performed at once, and the diseased parts, which will almost certainly be the cause of the peritonitis, removed. In deciding as to operation in chronic disease of the uterine appendages, the chief indication is the presence of a definite swelling which can be grasped bimanually. Where there is not a distinct tumour, and the disease is inferred from induration, fixity of the parts, and persistent pain, it is very likely that the pain is neuralgic, and the disease little more than thickening of the parts, from organized inflammatory effusion; and, in such cases, removal of the appendages, even if possible, is not likely to be followed by very great improvement.

In the hands of the most skilful operators the average mortality after removal of diseased and adherent uterine appendages is probably not less than 10 per cent.

The abdomen is opened in the middle line about half-way between the pubes and umbilicus by an incision from 2 to 3 inches in length. The peritoneal sac having been laid open and the uterine appendages identified by tracing them outwards from the fundus uteri, the adhesions are broken down and parts drawn up through the wound; then, the tube and ovary being held outside, the broad ligament is transfixed as near the uterus as possible and tied, and the part beyond the ligature cut off. If the stump do not bleed, the ligature is cut short and the stump dropped in. If there be much oozing from the torn adhesions, or if pus or other fluid have escaped into the abdomen, the pelvic cavity should be well washed out with plenty of warm water at a temperature such as the hand can comfortably bear. If washing with hot water fail to check hæmorrhage, the pelvis should be packed with hot sponges so as to press firmly on the bleeding point, and pressure kept up for some few minutes. If some point bleeds freely in spite of hot water and pressure, it may be touched with perchloride of iron. If the oozing be only slight, a Keith's drainage-tube should be put in and the wound closed round it, and it may confidently be expected that the hæmorrhage will cease. Any kind of clean dressing may then be applied. The treatment of the case is in other respects just as in other cases of abdominal section.

Tubercle of the Fallopian tube and Cancer of the Fallopian tube are rarely met with. Both conditions usually occur with similar disease elsewhere. Neither

has ever been diagnosed as a disease existing by itself.

Dilatation of the Fallopian tube at its uterine end is sometimes seen. Little or nothing is known of its ætiology. Its importance is, that fluids injected into the uterus may flow into the peritoneum through a dilated tube, and that the uterine sound may travel up a dilated tube, and so give an erroneous idea of the length of the uterus.

G. E. HERMAN.

FAVUS (Tinea Favosa; Honey-comb Ringworm) is a very chronic disease of the skin, due to the presence of a vegetable parasite, characterized clinically by the formation of cupped, sulphur-yellow plates in the epidermis, affecting usually hairy parts, especially the scalp, but sometimes spreading to hairless parts of the body.

The disease is very common in Poland and France. In Scotland it is still of not infrequent occurrence, but in England it is very rare, and is met with only among the most squalid of the lower classes, especially the Irish, and among the Polish Jews of the East-end of London, who usually import it. It is decidedly contagious, although much less so than ringworm, and frequently affects several members of the same family at the same time. It is also frequently contracted from dogs and cats, which, in their turn, derive it most probably from rabbits and mice.

Favus generally begins in childhood, and its duration is indefinite. It may last till advanced age, as long as hairs remain to provide a favourable nidus for the growth of its fungus. It begins in the scalp as a pinkish circular spot, which soon becomes covered with fine scurf, and sometimes exhibits faint vesication round the periphery. After about ten or fourteen days a minute yellow point may be seen round a hair, but in the thickness of the epidermis, and covered by some of its layers. As this increases in size to constitute the characteristic "plate" (*scutellum* or *scutulum*) its edge becomes considerably raised, but its attachment to the hair, where the epidermis is fixed down, persists, causing the typical central depression. This cupped plate usually shows some concentric marking, and increases until it attains the size of a split pea or fourpenny-piece, but is seldom larger. Although its central portion may become pale and whitish, its periphery retains the vivid yellow

colour; finally, it often ruptures the cuticle, which forms a loose, fringe-like appendage round its margin. As these plates grow in depth their convex undersurfaces form deep depressions in the rete, from which they can be easily "shelled" out with any blunt instrument, leaving a pit, the surface of which is usually smooth and moist, but sometimes bleeding and ulcerated. If of recent formation, these pits soon fill up again, but, if old, they are permanent, as atrophy of the true skin, and atrophic scarring, result from the long-continued pressure. The circular plates, when numerous, exert mutual pressure upon each other, and thus become hexagonal or polyhedral; and when a very large surface becomes involved they lose all form, and the scalp becomes covered with a mass of yellow crusts, intermingled with scabs, blood crusts and moist inflammatory products exhaling a peculiarly offensive "mousey" odour, almost, if not quite, pathognomonic of the disease. The fungus early penetrates the hair near the bulb, passing between the root-sheaths to ramify in the hair shaft, and causing it to become lustreless and friable, although it does not become broken, stumpy and twisted as in *tinea tonsurans*. Soon the hair is easily detached and falls off spontaneously, leaving large, bald areas, many of which are permanent. The co-existence of patchy baldness, atrophic scarring, and groups of yellow plates constitutes a typical picture, and the association with myriads of pediculi—which are probably responsible for the greater part of the inflammatory and impetiginous changes present—is almost invariable. Itching is usually moderate, although sometimes severe. On the body favus shows itself as ringed patches, very like *tinea circinata*, but seldom attaining large size. In the centre typical scutellum-formation generally occurs, and vesication often takes place at the periphery. Unlike favus on the scalp, it is easily curable, the fungus being confined to surface epidermis, and the follicles of lanugo hairs being shallow. The nails are sometimes also affected. The yellow fungus matter may show itself beneath the free margin of the nail, or may form beneath the nail, causing it to become opaque and thickened, with a tendency to splitting both transversely and longitudinally.

For the detection of the fungus of "achorion Schönleini" the crusts or hairs must be soaked in acetic acid or liquor potassæ, and the addition of

some ether is useful. The mycelium is somewhat similar to that of ringworm, but is not so fine; it is not so uniform in outline, but is often markedly moniliform or jointed. It breaks up into circular or polyhedral spores, larger than those of ringworm and coarsely nucleated.

Differential diagnosis must be established from ordinary impetigo of the scalp from severe seborrhœa, *tinea tonsurans* and psoriasis. Possibly the scars left might be confounded with those of lupus erythematosus, some syphiloderma, or even acne varioliformis. Microscopic investigation and careful attention to the preceding description will obviate all chance of error.

Treatment must be vigorously carried out for a prolonged period to effect cure when the scalp is affected, but removal of crusts from the body followed by any mild anti-parasitic application soon cures lesions there. The hair must be cut short with scissors; all scabs must be removed by poultices, or by rags soaked in oil, and the head covered with a flannel cap. Thereafter vigorous washing with hot water and soft soap must be carried out previous to the operation of epilation, which may be accomplished either by using broad forceps, which seize several hairs at a time, or fine forceps, which remove a single hair. After the daily epilation, inunction of some parasiticide is necessary, resorcin (3j ad 3j) and salicylic acid (3ss ad 3j) being probably the most potent and successful. When the nails are affected, their avulsion is necessary, and even then cure is very slow.

J. J. PRINGLE.

FEBRICULA.—A term loosely applied to a number of morbid states, of which fever is the prominent and predominant feature. It might be described as a morbid genus without essential attributes, consisting mainly of aberrant varieties of other determined species. The febrile disorders to which the term is applicable may be roughly grouped under the following heads:—

(1) Abortive or incomplete forms of the specific continued fevers—typhus, typhoid and relapsing fever. Cases of irregular type may occur at any time, but are more often met with during the epidemic prevalence of these diseases.

(2) Cases of scarlet fever, modified variola and more rarely measles and erysipelas, in which the eruption is either absent or unnoticed.

(3) In rare instances, anomalous forms of intermittent fever.

(4) Fevers due to the effects of some localized inflammation, in which the local signs are transient, ill-developed, or beyond the reach of observation. Cases of this sort occur in connection with lymphadenitis, tonsillitis, stomatitis and acute catarrhal affections of the alimentary and respiratory tracts.

(5) The group of fevers due to disorders of digestion, with absorption of pyrogenic substances through the gastric or intestinal mucous membranes.

(6) Cases in which the development of primary or secondary syphilis is attended by considerable febrile reaction, of which the source may not be easily discoverable.

(7) Fevers depending on some disturbance or exhaustion of the nervous system, as the consequence of exposure to excessive heat, or of some peripheral nerve irritation.

Febricula is very common among children, less frequent among young adults, and somewhat rare after thirty.

Symptoms and Course.—The only symptom common to the whole group is pyrexia, and in not a few cases it constitutes the whole disease. This applies especially to young children, in whom a sudden rise of several degrees in the body temperature may constitute the only appreciable deviation from health. The invasion is generally sudden, but may be gradual. The temperature may reach 104° F. or even higher, especially in children. In adults the onset is sometimes attended by chilliness or distinct rigors. Nausea and headache are also common initial symptoms. In children there is often sickness; more rarely the disorder is ushered in by a convulsion. The febrile blush is often well marked, and must be distinguished from the eruption of scarlatina, with which it may be confounded. During the acme of the fever, which generally lasts from twelve to forty-eight hours, more rarely for three or even four days, the ordinary concomitants or symptoms of fever are present in varying number and degree. The pulse and respirations are always increased in frequency. In children the *alæ nasi* are easily set in action, and rhonchi and crackling râles may occur in the lungs, disappearing when the temperature falls. Herpes labialis is sometimes met with. Restlessness and disturbed sleep are usually present, and there may be slight delirium. Constipation is the rule, with slightly furred

or red and irritable tongue. There is usually disinclination for food, and in children thirst is nearly always excessive. The urine is scanty and high-coloured and deposits lithates on cooling.

In some cases the symptoms of gastrointestinal derangement predominate; in others the brunt of the affection falls on the respiratory tract, whilst in a third group the disturbances of the sensorium overshadow all other symptoms. In these rarer cases of cerebral type, which are almost peculiar to children, headache, repeated vomiting, intolerance of light and irritability or stupor, with or without delirium, are the chief symptoms.

The temperature generally falls by crisis, and is attended by an immediate remission in the symptoms. Convalescence is always rapid.

Diagnosis.—This rests chiefly on the exclusion of other acute fevers. Typhoid fever, pneumonia, meningitis and scarlet fever are the diseases from which the diagnosis is most difficult in the early stages. The occurrence of a sharp attack of fever in a previously healthy child is in favour of febricula. It must, however, be borne in mind that what at the outset appears to be simple fever may develop into some severe and even highly infectious disease. And, further, some forms of febricula appear to be infectious, as, for instance, the so-called feverish cold. A knowledge of these facts should enjoin both care and prudence in the treatment of these affections.

The *prognosis* is always favourable.

Treatment.—Rest in bed, with simple diet, for a day or two, will suffice in most cases. Cooling drinks and diaphoretics are pleasant and harmless. Constipation should always be relieved by appropriate means. Castor oil and calomel are amongst the most efficient remedies in the treatment of these affections. Antipyretic treatment is not called for.

WILLIAM PASTEUR.

FEVER (Pyrexia) may be defined as a certain disorder of the body-heat usually characterized by a rise of temperature.

In most of the diseases presenting the symptom of pyrexia, there are other symptoms, which are now regarded as either (1) secondary to the exciting cause of the primary disease, or (2) secondary to the symptom of pyrexia.

In the latter group have been placed—quickening of pulse and breathing, nervous disturbances, such as delirium or

coma, digestive disturbances, such as loss of appetite and sickness, disturbance of the salivary, sudorific, renal and other secretions, wasting and degeneration of the muscles and of some other tissues. But though these symptoms enter into the ordinary clinical conception of fever, they are not essential to it, the only essential feature being the disorder of the body-heat.

In *health* the temperature of the body, though not perfectly *constant*, is nearly so. Taken in the mouth its daily range for an adult is from about 97.6° F. to 99.6° F. But within this range the temperature is *stable*; in other words, causes external or internal which tend to raise or to lower it beyond the normal at the same time call into play physiological agencies which counteract any such effect.

We have to consider the nature of these agencies. To maintain a stable temperature different from that of the surrounding medium, the body must possess (1) means of producing heat (thermogenesis); (2) means of easting off or discharging heat (thermolysis); and (3) means of automatically adjusting the balance of (1) and (2), whatever their separate variations may be (thermotaxis).

Thermogenesis.—The chief source of heat within the body is the chemical change or oxidative metabolism continually going on in the muscles, and to a much less degree in the glands and alimentary tract during digestion. The muscles may be regarded as “the thermogenic tissues *par excellence*.” The metabolism subserving heat production in the muscles is under nervous control, like that which results in contraction or motion. The thermogenic nerves are closely associated with the motor nerves, but they are probably not identical with them. Gaskell has shown, moreover, that in the case of the involuntary muscles and of the heart the motor nerves are accompanied by others whose function is inhibitory. These cause the contracted muscle to relax, and at the same time set up chemical changes in it which are not oxidative or destructive, but restorative or reconstructive. The motor nerves are, therefore, described as catabolic, the inhibitory nerves as anabolic.

It is assumed that the thermal nerves are also twofold, the catabolic inducing oxidation and the development of heat, the anabolic inducing reconstruction and the inhibition of heat production. Various points in the track of the thermal nerves through the spinal cord and brain have

been discovered, the most important being about the inner and anterior aspect of the corpus striatum (the so-called “heat centres”).

Thermolysis.—The chief avenues by which heat is discharged from the body are the skin and the lungs, about 80 per cent. normally escaping by the skin and less than 20 per cent. by the lungs. These avenues are each controlled by a twofold nervous mechanism. The thermolysis of the skin depends chiefly on the flow of blood through its vessels, whose calibre is increased by the vaso-constrictor (or catabolic) nerves and diminished by the vaso-dilators (or anabolic) nerves, each set having appropriate “centres” in the cord and medulla oblongata. The discharge of heat by the lungs, more important perhaps in the lower animals than in man, depends on the rapidity and depth of the respirations, and these are likewise known to be controlled by a twofold nervous apparatus in the central nervous system. Thermolysis, therefore, like thermogenesis, may be regarded as subject to nervous control, which is on the one hand excitator or catabolic, on the other inhibitory or anabolic.

Thermotaxis.—As the mechanisms of heat production and heat loss are thus essentially nervous, that which adjusts their balance in health must also be nervous, and, like other adjusting and co-ordinating mechanisms, must be higher than either—higher in complexity of organization, and higher and later in the scale of evolution. In it, to use Hughlings Jackson's expression, the lower and more automatic mechanisms must be “represented.” As it is more complex and less automatic, it is likely to be more easily disordered, and less definitely localized in the central nervous system than the thermogenic and thermolytic mechanisms. On this account we as yet know little of its anatomical seat, and of its normal mode of working. The like is true, and for a like reason, of the higher motor, sensory and mental nervous mechanisms.

Temperature.—The temperature of the body at any moment is not, *per se*, a measure either of heat production or of heat loss. So long as the heat discharged is equal to that produced, the temperature remains constant, whether its level be high or low. If heat loss lag behind heat production, the temperature will steadily rise until heat loss becomes equal to and overpasses heat production, when the temperature will fall again. Thus a low temperature may co-exist

with excessive thermogenesis if thermolysis be adequate, and a high temperature may co-exist with diminished thermogenesis if thermolysis be inadequate. Thus the mere fact that in pyrexia the temperature is usually raised does not prove either that thermogenesis is increased or that thermolysis is diminished.

Thermal Ataxia.—If the thermotaxic mechanism be disordered or weakened without any serious disturbance of the other two thermal functions, these latter may vary independently, and, as there is nothing to bring them constantly to a balance, the body temperature undergoes large and irregular fluctuations. Of this nature are probably the “paradoxical” or “hysterical” temperatures sometimes recorded, which may for a short time rise to 110° F. or more, and that without grave or permanent lesion. The rise of temperature is not evidence of pyrexia, and its fall is not defervescence; the condition is one of inco-ordination, and may be fairly described as thermal ataxia.

Pyrexia.—When the thermotaxic mechanism is disordered or weakened, and thermogenesis is at the same time morbidly and continuously increased, we have the condition of fever or pyrexia. Experiment and observation have alike shown that the high temperature which usually characterizes fever is due, not to continuously diminished discharge, but to greatly increased production of heat. Thermolysis is, indeed, proceeding at an abnormally active rate, and though at first it may lag behind, it at length overtakes thermogenesis. Thus the temperature does not rise continuously, but after a while fluctuates, at a high level indeed, but within moderate limits, for days together. At the same time, thermotaxis being enfeebled, the high temperature of pyrexia is essentially *unstable*, and may be raised or lowered by disturbing causes which in health would be quite ineffective. The increased thermogenesis occurs chiefly in the muscles, and is due not only to continuous over-action of the catabolic or excitator nerves, but to paresis or under-action of the anabolic or inhibitory nerves. The result is excessive oxidative or destructive metabolism, and deficient constructive or reparative metabolism of the muscular tissue. This is evidenced clinically by the excessive discharge in the breath of carbonic acid, and in the urine of nitrogenous waste products (excessive as compared with those derived from the food

taken), and by the visible wasting and enfeeblement of the muscles.

Hyperpyrexia.—If the nervous disorder be more profound, affecting alike thermotaxis, thermogenesis, and thermolysis, the latter may fail altogether to overtake the excessive heat production, with the result that the temperature steadily rises until the disorganization ends in death. This condition, which without prompt and adequate treatment is almost always fatal, is called *hyperpyrexia*. Cases, indeed, occur in which the temperature continues to rise after both respiration and circulation have ceased, the thermogenic activity of the muscles, like their contractility, surviving somatic life, while physiological thermolysis is in abeyance.

Ætiology.—The nervous disorder which shows itself as fever may be occasioned by lesions which are (1) thermal, (2) mechanical, or (3) chemical; to these we may add (4) reflex, though it is not certain that this group of causes is unrelated to the others.

(1) *Thermal.*—Prolonged exposure to hot air or water, by which, in the first place, the normal loss of heat from the skin by radiation and evaporation is checked, and, in the second place, the thermotaxic and inhibitory thermal mechanisms are at length exhausted or damaged owing to the continued strain upon them, gives rise to fever. This is usually accompanied by other signs of nervous disturbance, such as delirium or coma, and is known as sun- or heat-stroke, or heat-apoplexy. The thermal disorganization is very apt to pass into the graver form of hyperpyrexia.

The rational *treatment* is by every means to abstract heat from the body, and this is best done by the immediate and persistent application of ice or cold water.

(2) *Mechanical.*—Tumours, hæmorrhages, embolisms, structural degenerations and traumatic injuries, whether in the brain or the spinal cord, may, if they involve the proper thermal tracts or centres, give rise to pyrexia. But similar lesions may equally well cause thermal ataxia, and if thermogenesis be checked or thermolysis increased, they may cause a fall and not a rise of temperature. Cases of each kind are on record.

(3) *Chemical.*—Substances which act injuriously on the nervous system, and especially on the thermal mechanisms, may reach them through the blood, and are probably the commonest causes of

fever. They may be produced (*a*) within the tissues themselves, when they are the result of morbid metabolism, *e.g.* in rheumatism, or of normal waste which has failed to be eliminated, *e.g.* in gout; or (*b*) in some natural or morbid cavity of the body the result of the action of living micro-organisms on blood or tissue or secretion (specific infective diseases, pyæmia, septicæmia); or (*c*) without the body, being introduced by injection into the blood (atropine, certain albumoses).

(4) *Reflex*.—The best example is probably the “urethral fever,” which in some sensitive persons immediately follows the introduction of a catheter. Of this kind may be also the pyrexia which accompanies sudden and very painful injuries and local inflammations without suppuration, but associated with painful tension.

Clinical Terms.—The temperature is the most convenient index of pyrexia, though we have seen that it is not a perfect one. In this respect it resembles the state of the tongue, which, with certain reservations, indicates the condition of the digestive tract, and the state of the pulse, which tells us much, but not everything, of the condition of the circulatory system.

In most cases of pyrexia the temperature rises (onset), continues with moderate fluctuations for some days (acme), and then falls (defervescence), either suddenly (crisis) or by a succession of steps (lysis), to or below the normal. If the fall extend much below the normal, we have “collapse,” often a fatal sign. This is the type of a so-called “continued” fever, and is characteristic of many of the specific infective diseases.

In “hectic” (or habitual) fever, characteristic of tuberculosis, there is, for an indefinite period, a daily evening rise and morning fall of temperature, the fluctuations being large (3° to 5° F.) and rather irregular.

In “intermittent” fever, which is practically synonymous with ague (malarial fever), every day (quotidian), two days (tertian), or three days (quartan) there is an abrupt rise, a brief acme, and a crisis, the whole occupying only a few hours, and the temperature between the attacks being normal.

In “remittent” or relapsing fever we have a succession of attacks of continued fever, each lasting for a few days, and separated by intervals free from pyrexia.

Temperatures are also classified according to a rough clinical scale origin-

ally proposed by Wunderlich, who may be called the founder of clinical thermometry. Thus, temperatures of—

99.5° to 100.4°	arc sub-febrile.
100.4 „ 101.3	„ slightly febrile.
101.3 „ 103.1 (evening)	„ moderately febrile.
103.1 „ 104.9 (evening)	„ markedly febrile.
Higher temperatures	„ highly febrile.

Recovery.—In the Gulstonian Lectures for 1887, delivered by the writer, the process of recovery from a typical febrile attack is thus described:—“First, the thermolytic mechanism is waked to adequacy, there is a critical sweat or a relaxation of the vessels of the skin, and a gush of heat from the surface brings down the temperature with a run. But the thermogenic centres have not yet recovered, and the temperature will swing backwards and forwards for some days, and an epicrotical excretion of urea takes place. Thermogenesis becomes less and less excessive, and is vigilantly counterbalanced by thermolysis; but thermotaxis is yet feeble. The patient’s temperature is down, but it is yet far from stable. As convalescence proceeds the stability increases, thermotaxis, the first to be disturbed and overthrown, being at last restored.”

Treatment.—The treatment of a disease accompanied by fever must be directed chiefly to the removal or modification of the primary cause of the disease. When this cannot be done, and when the fever, either by reason of its duration or of its intensity, becomes itself a source of danger, it is advisable to employ antipyretic methods. These are directed, first, to increase thermolysis; secondly, to diminish thermogenesis. We have no certain knowledge of any whose chief or primary action is on the thermotactic mechanism.

Heat loss may be increased with advantage, especially where the skin is dry, by increasing its vascularity and stimulating its sweat glands. For this purpose, alcohol in small and frequent doses, spirit of nitrous ether, and solution of the acetate of ammonium, with abundance of water to drink, are the simplest agents. In the earliest stage, aconite (1 minim of the tincture every five minutes till 30 minims have been given) has a useful effect in relaxing the superficial arterioles, and so discharging heat from the skin; but it is of little

value when the fever has reached its height. Heat may also be actively abstracted, and in long-continued fevers with the best results, by the use of the cold or gradually cooled bath. In rheumatic fever, and especially in enteric fever, its efficacy in preventing exhaustion, in promoting comfort and refreshing sleep, and in averting danger to the brain and tissues is now beyond dispute. Simple sponging or other local application of cold is soothing but of comparatively small value as an antipyretic method. The patient should be immersed for from four to ten minutes in an ample bath, the water being at a temperature of 65° to 70° F., and the bath should be repeated as often as the temperature rises to a certain point. This point will depend on the severity and course of the disease; thus, in moderately severe cases of enteric fever it may be fixed at 102.5° F., in rheumatic fever with a tendency to hyperpyrexia, at 103.5° F. In the somewhat rare instances when the patient evinces great repugnance to the cold water, he may be immersed in a tepid bath at 80° F.; the temperature of the water may then be lowered by the addition of pieces of ice. On removal from the bath he should be very lightly covered. This method has been more thoroughly pursued on the Continent than in this country, and Naunyn, after a large experience of it, is able to say, "I consider it proven, as a matter of statistics, that the cold-bath treatment of enteric fever shortens the duration of individual cases, and, above all, very considerably reduces the mortality—namely, from 15 to 20 per cent. to 5 to 10 per cent."

Of drugs whose action is to check thermogenic metabolism, either directly within the muscles or through the nervous system, we have now a large and increasing number. Quinine in full doses (10 to 20 grains once or twice a day), and salicylic acid, with its allies, salicin and the salicylates (*e.g.* 20 grains of sodium salicylate in solution every three or four hours), are the more familiar of these; they tend to allay the pyrexia of almost all diseases, but quinine is much more efficacious in intermittent than in continued fevers, and the salicyl compounds in fevers due to rheumatic causes than in any others.

Chinolin, resorcin, kairin, thallin, have all marked antipyretic qualities, but their occasionally excessive action and other grave disadvantages have caused them to fall out of use in fever. The more

recent products of synthetic organic chemistry, to which the trivial or non-systematic names, antipyrin, antifebrin, phenacetin, methacetin, pyrodon, and so on, have been given, are in many respects superior, and have come largely into use. Of these, antipyrin is the most to be recommended; it has more advantages and, on the whole, fewer drawbacks than any of the others. It may be given in doses of 15 grains, dissolved (say) in cinnamon or camphor water, at intervals of four to six hours when it is desired to maintain the temperature at a point not higher than 100° F., and this effect may be maintained for several days by slightly shortening the intervals between the doses. It is also useful as an adjunct to cold applications in cases of heat-stroke. In a small proportion of cases it causes an erythematous rash, which is harmless, and disappears in three or four days.

Antifebrin is cheaper than antipyrin, and the effective dose is smaller (3 to 5 grains); but it is much less soluble, and is too apt to give rise to cyanosis or to anilin-poisoning. Phenacetin is also nearly insoluble; it is best given in powder or lozenges (5 to 10 grains), and its action on the temperature is gradual and very durable (eight to ten hours). In ordinary doses it does not produce any untoward effects. All three drugs are apt to give rise to profuse perspiration, but this in itself is no disadvantage. Pyrodon depresses the temperature very powerfully, but it is a dangerous drug, and should be avoided in ordinary practice. These antipyretics have all valuable analgesic and other properties, which, however, need not be referred to here. They produce no obvious effect on the primary disease, and their main action is in all probability exerted on the thermogenic mechanism, stimulating inhibition and depressing over-activity. The improvement in the patient's condition they produce seems to be entirely dependent on the assuaging of his pyrexia. They should be avoided in cases where the heart is flagging or actively diseased (myocarditis, ulcerative endocarditis, diphtheria), after great hæmorrhage, during the catamenia, in massive pneumonia with pulmonary œdema, and in the late stages of tuberculosis or other long-continued and exhausting malady. As a general rule, they should at first be administered in small doses, the effect on the temperature and on the heart being observed: this will give data for determining the

amount and frequency of the dose appropriate to the particular case.

DONALD MACALISTER.

FILARIA SANGUINIS HOMINIS—An embryo of a minute nematode worm which infests human beings in certain tropical climates.

The female is "a long slender hair-like animal quite 3 inches in length, but only $\frac{1}{16}$ inch in breadth, of an opaline appearance, looking, as it lies in the tissues, like a delicate thread of catgut animated and wriggling. A narrow alimentary canal runs from the simple club-like head to within a short distance of the tail, the remainder of the body being almost entirely occupied by the reproductive organs. The vagina opens about $\frac{2}{5}$ inch from the head; it is very short, and bifurcates into two uterine horns, which stuffed with embryos in all stages of development, run backwards nearly to the tail" (Manson). The male is considerably smaller than the female.

The parent worm inhabits the lymphatics; into these the embryos are discharged, and, making their way into the thoracic duct, reach the blood. They can, however, be found in the blood only during certain hours, as a rule between 6 P.M. and 9 A.M., but Dr. Stephen Mackenzie has shown that by reversing the habits of the patient, making him sleep in the daytime and keep awake at night, the filariæ make their appearance in the day instead of at night.

The life history is as follows:—A particular kind of female mosquito sucks the blood of a person infected with filariæ, and thus swallows some of the embryos. Five or six days afterwards she deposits her ova on some pond, and dies. Meanwhile, most of the embryos have died, but some may have undergone development and transformation, and are now possessed of a head with papillæ, an alimentary canal and rudimentary generative organs. In this state they are liberated from the body of the mosquito, but it is not known with certainty how they get into the human body—possibly through the drinking water.

From the human stomach they at once pass into the lymphatics, where they remain permanently located. Though constantly discharging large numbers of embryos into the lymphatics, their presence may give rise to no symptoms at all, and it is only when the ova are prematurely discharged that ill results occur. The embryos, when fully developed, are extremely narrow, elongated, encapsuled

bodies, capable of passing the most minute capillary network, but at an earlier stage of their development they are round, and of much greater diameter. When, therefore, they are prematurely discharged, being carried by the lymphatics to the nearest gland, they are there arrested. In this way complete lymphatic obstruction is brought about, and the diseases known as elephantiasis, lymphoscerotum, and chyluria (*q.v.*) are the result, according as the lymphatics of the legs, scrotum, or pelvis are obstructed.

JOHN ABERCROMBIE.

FLUCTUATION.—When fluid is present in a cavity, if the hands be placed at opposite points on its walls and a sharp tap be given with a finger of one hand, a shock is felt by the other. This sign is termed "fluctuation," but the same term is also used to describe the sensation received when alternate pressure is made over an abscess or through a joint containing fluid. In the case of a cavity it is essential that it should not be very small nor the fluid too thick. When the abdomen is very tense, it may be necessary for an attendant to place the edge of his hand along the linea alba in order to arrest the vibrations of the abdominal walls which are produced when a tap is given to the side, otherwise they may be mistaken for the fluctuation of fluid within the peritoneum.

FOMENTATION.—When the local effects of heat are needed, but the use of a poultice is not desirable, a fomentation will generally best fulfil the indications. It may be moist or dry. If the former be preferred, a flannel or cloth is placed in boiling water, then thoroughly wrung out and applied to the part as hot as it can be borne, and covered with oiled silk or waterproof. As compared with poultices, hot fomentations have the advantages of being more cleanly and lighter, the disadvantages being that they cannot be used where there is an open wound, and that they speedily lose their heat, and therefore require to be changed frequently—every half-hour or so. Hot moist fomentations are especially useful in cases of peritonitis, and in renal and other forms of colic. Their action may be aided by the addition of a few drops of turpentine (the so-called turpentine stupe), or, if a sedative effect be desired, by sprinkling a drachm or more of laudanum over the flannel, or by using

a decoction of poppy-heads¹ instead of boiling water. The decoction is prepared by boiling $\frac{1}{2}$ lb. of poppy-heads in 2 quarts of water for ten minutes, straining and allowing the clear fluid to stand by the fire. Instead of cloths or flannel, spongio-piline may be used in a precisely similar way, and it has the advantage of retaining the heat rather longer. Sometimes dry fomentations are preferable; for this purpose either hot bran or chamomile flowers are applied in bags, or a piece of flannel or cotton-wool simply warmed in front of the fire. This method is particularly applicable for the relief of earache or colic.

FOURTH NERVE, Diseases of the.—This nerve, which emerges from the valve of Vieussens and courses round the outer surface of the crus cerebri to supply the superior oblique muscle in the orbit, is liable to be paralysed from neuritis due to syphilis, from compression by tumours at the base of the brain, by an aneurysm of the internal carotid, and by growths in the orbit. The nucleus in the upper part of the floor of the fourth ventricle is liable to be destroyed by tumours inside the pons, and may undergo atrophy in association with the other ocular nuclei, as in ophthalmoplegia externa.

The *symptoms* are diplopia and a slight amount of paralysis, observed when the patient looks downwards. The action of the superior oblique is to direct the eyeball downwards, and at the same time to rotate it so that the upper end of its vertical axis comes nearer to the middle line; the defect of movement is therefore downwards and inwards, but it is often too slight to be noticed. Diplopia is present on looking downwards, and the false image is below the true one, and its upper end is tilted towards the middle line of the body. This obliquity is increased by looking outwards, whilst the difference in vertical level between the two images is increased by looking inwards. The obliquity of the false image is due to the loss of rotation inwards of the upper end of the vertical axis of the eyeball. What is called the secondary deviation of the sound eye is in a direction downwards and inwards. To obviate the diplopia the patient inclines his head forwards and towards the sound side.

Treatment.—As syphilis is the most common cause of paralysis of this nerve, iodide of potassium should be given in

large doses. When the lesion is due to the presence of a tumour, the same treatment is advisable, as the growth may be of syphilitic origin.

C. E. BEEVOR.

FRAMBÆSIA (Yaws; Pian; Endemic Verrugas).—A tropical, contagious disease, endemic in the West Indies, South America and Africa, chiefly affecting the coloured races, and of especial frequency between the ages of ten and twenty years. The disease begins with feverish symptoms and severe pains in the limbs, followed by mottling of the skin and branny desquamation. Papules and flat tubercles, sometimes as large as peas, then appear, and are distributed all over the body, but most thickly over the exposed parts. The tubercles break down, discharge a thin yellow fluid, and ulcerate. From the ulcers thus formed the red, fungating, raspberry-like excrescences characteristic of the disease arise. The affection runs a definite course, and generally subsides within two years. One attack affords protection against a second. No scars result from the ulcers. Competent authorities, thoroughly familiar with the disease, consider it to have no relation to syphilis, and it is said to be aggravated by the administration of mercurials.

Treatment.—The disease is uninfluenced for good by treatment.

J. J. PRINGLE.

FRECKLES are minute, irregularly shaped accumulations of the normal pigment of the skin, varying in colour from fawn-yellow to deep brown. They never occur in very young children or in advanced age. They are commonest in fair people, especially those with red hair and fine complexion, are usually most marked on the face and backs of the hands, and are aggravated by exposure to the sun, although not primarily due to it, as they occur ("cold freckles") upon parts of the body seldom exposed to its rays, especially on the buttocks, back and penis. They generally first appear in summer and partially disappear in winter. Freckles frequently give rise to considerable disfigurement, but cause no subjective symptoms.

The *treatment* is that of chloasma (*q.v.*).

FREMITUS.—Vocal fremitus is the thrilling sensation conveyed to the hand when applied to the chest of a person during phonation.

The nature of the sensation perceived will depend upon the character of the voice, there being wide differences in this respect. The deep tones of a man's voice are always much better conducted than the higher-pitched voice of a woman or child. The amount and kind of the tissues interposed between the hand and the lung will also influence the vocal fremitus, which is usually more marked in lean persons. Any condition which produces consolidation of the lung will increase the vocal fremitus, provided the bronchi be patent; whilst the presence of fluid between the lung and the chest wall will diminish it, or altogether prevent its being felt.

The vocal fremitus beneath the right clavicle is normally more distinct than on the opposite side. If, therefore, the vocal fremitus be equal on the two sides, and well marked, it is probably increased at the left apex, and a presumption arises that the left upper lobe is the seat of disease. If the fremitus be more marked at the left apex than the right, the presumption that the left upper lobe is affected is still stronger. If, on the other hand, the vocal fremitus beneath the clavicles be equal, but less marked than normal, probably the voice conduction is diminished at the right apex, and the condition of the right upper lobe must be carefully investigated in the further course of the examination. What has been stated as to the conditions and significance of the vocal fremitus beneath the clavicles applies equally to the supra-spinous fossæ.

Rhonchal fremitus is felt when the vibrations produced by the passage of air through a large bronchial tube, narrowed by the presence of mucus, are sufficiently intense to reach the hand applied to the chest. It is often present in bronchitis, and is especially frequent in the case of children suffering from that disease.

Friction Fremitus.—The vibrations produced by the rubbing together of two dry surfaces of the pleura, and very rarely of the pericardium also, may sometimes be appreciated by the hand. The above term is used to indicate this sign. It is not uncommonly present in cases of dry pleurisy.

Tussive fremitus is felt when the hand is placed upon the chest whilst the patient coughs. It is sometimes of use in diagnosis in the case of children, and in adults when the condition of the voice prevents the conduction of the vocal fremitus.

Hydatid fremitus is the sensation occasionally elicited by percussion over the site of an hydatid tumour, usually of the liver. Three fingers are placed over the site of the tumour, and the middle one is sharply percussed, when a thrilling sensation may be perceived by the other two. This sign is present in only a very small proportion of cases, and is therefore of comparatively little value in diagnosis. J. K. FOWLER.

FRICTION SOUND is the name given to the rubbing, crepitant, or creaking sound heard on auscultation over the large serous sacs when their ordinarily smooth surfaces are roughened, usually by an inflammatory exudation.

In the case of the *pleura*, apart from the rubbing nature of the sound, its evidently superficial character, and the fact that it is usually audible both with inspiration and expiration, help the diagnosis; but it is often very difficult to decide whether a sound having a crepitant character is of pleural or pulmonary origin. If the sound be audible only at the end of a deep inspiration, if it remain unchanged by cough, and if there be localized pain increased by inspiration, it is probably due to the presence of a patch of recent lymph on the underlying pleura, or of fine fibrous adhesions. The pleural origin of a crepitant sound is often indicated by the discovery of a "rubbing" friction sound in its immediate neighbourhood.

A pleural friction sound in the precordial area may acquire a "to and fro" character under the influence of the movements of the heart. Such a sound usually ceases when the lung is fixed by holding the breath after a deep inspiration.

Pericardial friction sound may be single or double, occurring with either systole or diastole of the auricles or ventricles, or with both.

It may be distinguished from a valvular murmur, for which it is liable to be mistaken, by its rough and superficial character, by the fact that it is not most distinct at the normal sites of maximum intensity of valvular murmurs, and often from its want of exact synchronism with the systole or diastole of the ventricles (*see* PERICARDIUM, DISEASES OF).

Peritoneal friction sound is most often heard over the region of the liver, as the organ moves during respiration, and indicates the presence of peri-

hepatitis, which may be either a local affection or part of a general inflammation of the peritoneum. It may be occasionally distinguished over other areas of the abdomen when the serous membrane is roughened by inflammation, or from the presence of morbid growths.

J. K. FOWLER.

FROSTBITE is a form of inflammation of the skin and deeper parts produced by prolonged exposure to cold, and tending to terminate in gangrene.

The parts chiefly affected are the fingers, toes, tips of the ears, and nose, where the circulation is weak and a large extent of surface is exposed to the air. In this country fatal exposure to cold is rare.

Anæmic persons of either sex are specially prone to suffer, and in them a temperature several degrees above freezing-point may be sufficiently low to cause frostbite.

Symptoms.—The milder forms of the

conditions are described under the heading of **CHILBLAIN** (*q.v.*). In the more severe forms, the part attacked is at first pale, wax-like or mottled, and senseless; afterwards, it becomes covered with bullæ, the contents of which are often hæmorrhagic. The accompanying general phenomena are those produced by excessive cold (stupor, somnolence, coma). When thawing is complete, an inflammatory line of demarcation between the healthy and gangrenous parts shows itself. Days, or even weeks, may, however, elapse before the amount of tissue which has been actually destroyed can be determined.

The *prognosis* ought always to be somewhat guarded, more especially in the case of infants and old persons. Death often results from phlebitis and septicæmia.

The *treatment* of the milder forms is described under **CHILBLAIN**. In severe cases, amputation must be performed after the formation of a distinct line of demarcation.

G

GALL-BLADDER, Diseases of.

—The gall-bladder is liable to various diseases, in part originating in itself, in part depending upon its relation to the bile ducts, in part, again, secondary to diseases of the liver or of adjacent organs.

Dropsy.—When the cystic duct becomes occluded by a gall-stone or a parasite, or, as the result of inflammation or of some morbid growth, no bile can find its way into the gall-bladder, which may become distended with a clear watery mucus secreted by its lining membrane. This is called dropsy of the gall-bladder, and the result is the formation of a pyriform elastic tumour, to be felt on the right of the middle line, in the normal portion of the gall-bladder, or possibly much lower down in the abdomen. In several instances such tumours have been so freely movable and so far from the normal situation as to have been diagnosed as floating kidney.

The *symptoms*, apart from the presence of the tumour, may be negative. There may be *pain*, and this is generally the case when the condition comes under notice.

Treatment is only called for when pain is present, and in such cases cure has followed the operation of opening the

gall-bladder after abdominal section and stitching its walls to the edges of the wound. A fistulous opening may remain for some time, but generally closes eventually.

Inflammation.—By extension of catarrh from the biliary ducts the mucous membrane of the gall-bladder may become involved. Acute catarrh is generally caused by extension of a similar inflammation from the duodenum; chronic catarrh, on the other hand, often occurs in chronic congestion of the liver, as in heart disease. But both may be caused by direct irritation of the cystic mucous membrane by abnormal bile, gall-stones, or parasites in its cavity. These last are also prone to set up a form of inflammation in which the lining is covered with false membranes, or may even cause phlegmonous inflammation, with suppuration and ulceration. Phlegmonous inflammation may also be caused by extension from an abscess in the liver. Ulcerative inflammation is apt to pass on to gangrene.

In all these conditions the affection is but part of a complex of symptoms. These are described under the diseases to which they properly belong, and with which their prognosis and treatment are necessarily involved.

Ulceration may lead to the formation of *biliary fistule* communicating either with the intestine or the internal surface of the body.

New Formations.—Cancer of the gall-bladder is so often associated with the presence of gall-stones (*q.v.*) that it is probable that the irritation they set up determines its occurrence. The gall-bladder may also become involved in cancer of the stomach, intestine, bile ducts or liver.

Parasites.—The gall-bladder may be invaded by various parasites, especially by *distoma hepaticum*, *ascarides*, and *hydatids*. The presence of any of these may give rise to symptoms of obstruction of the cystic duct, or may cause inflammation and even ulceration of the cystic mucous membrane.

ROBERT SAUNDBY.

GALL-STONES.—The gall-bladder frequently contains calculi, which may be single or multiple, as large as a pigeon's egg, or as small as sand, faceted or rounded, or presenting numerous small roughened excrescences on their surfaces. Such concretions are often found post-mortem in the bodies of persons who have in nowise suffered from their presence during life.

They are composed of cholesterine, bile pigment, bile acids, fatty acids, salts of lime and magnesia, mixed with mucus, sodium chloride, iron and water.

The chief component is cholesterine, and sometimes pure calculi of this substance are met with.

The formation appears to depend upon the precipitation of cholesterine and bile pigment from deficiency of sodium salts in the bile. In addition, the presence of lime appears to favour this precipitation, as this earth readily forms insoluble salts with the bile acids (Bonchard). A third factor is to be found in the concentration of the bile, which takes place rapidly when it remains long in the gall-bladder, so that any circumstances which favour the retention of bile in this situation also favour the formation of calculi.

It follows from the foregoing that gall-stones are prone to form in persons who take large quantities of highly nutritious food, who use water strongly impregnated with lime, and whose habits are sedentary. There is a close, but not constant, relation between obesity and gall-stones, and, in addition, sufferers from biliary calculi frequently also pass uric acid stones from the kidneys.

Heredity and gout both play an im-

portant part in the ætiology, and the general causes of the uric acid diathesis may all aid in the production of the affection. In addition, tight lacing, habitual constipation, and pregnancy are alleged to favour its development.

Biliary calculi are most common between the ages of twenty and forty years. Females are much more often affected than males; the proportion of liability has been estimated as high as 4 to 1.

Symptoms.—As has been already stated, gall-stones may be present for many years, and in large numbers, without giving rise to symptoms, which are not usually very acute unless the calculus become involved in the cystic or common bile duct. This happens in consequence of active peristalsis in the gall-bladder, such as occurs during digestion, but it is especially from the use of purgative medicines acting on the duodenum that the violent contractions which precipitate an attack of biliary colic are induced.

The calculus may ulcerate through the wall of the gall-bladder, and escape into the duodenum, the colon, or the peritoneal cavity and set up peritonitis, or may, after the formation of an abscess, be discharged externally through a fistulous opening in the integuments. Of these events the first named is the most common. If a calculus of large size pass into the duodenum, it may subsequently cause intestinal obstruction (*q.v.*).

The symptoms of gall-stones are mainly observed in the acute attack, called **biliary colic**, which is characterized by pain in the hypochondrium of an excruciating character, radiating all over the thorax, and often accompanied by agonizing pain between the shoulders, with a general sense of constriction of the chest. It is noteworthy that the pain of biliary colic is mainly thoracic, while that of renal colic is abdominal. With the pain, which is often so intense as to cause the patient to roll about, cry out and sweat profusely, there is *vomiting*, which seems to give some relief to the pain. After an hour or more the pain abates, but there remains considerable tenderness in the region of the gall-bladder, and frequently, if palpation be possible, a tumour due to the distended gall-bladder can be felt.

Jaundice is not an essential part of this complex of symptoms. Obviously, no jaundice will be caused unless the stone pass along the cystic duct and get impacted in the common duct. But probably many stones, after getting into the cystic duct, drop back into the gall-bladder; whereas others which are large

enough to cause great agony whilst passing along the slender cystic duct, are not too large to pass through the common duct, and to escape into the duodenum without difficulty.

A *local rise of temperature* over the region of the gall-bladder is stated to occur (Peter), and is held to furnish valuable diagnostic information.

When the stone gets impacted in the common duct, very persistent jaundice may result, and the liver may become enormously enlarged, all the ducts being dilated by the accumulated bile, so that the organ comes to resemble in texture a large sponge full of bile. As the result of septic changes, the retained bile may become transformed into pus, the liver being found on autopsy to be riddled with small abscess cavities.

The stone, after obstructing for a time the common duct, may slip back again into the cystic duct or into the gall bladder, the flow of bile becoming temporarily re-established and the jaundice disappearing, a sequence of events which may be several times repeated. In other cases the liver undergoes interstitial inflammation, and becomes cirrhotic, forming one type of "hypertrophic cirrhosis."

Gall-stones give rise to inflammation of the gall-bladder, and in some cases the cavity may become distended with pus, causing a tumour similar to that described as the result of dropsy, and which has been successfully treated in the same way. There is also reason to believe that they are capable of giving rise to irritation, which leads to the formation of cancer (*vide supra*).

The presence of stones in the gall-bladder sometimes gives rise to attacks closely resembling ague—chills followed by fever, and terminating by sweating.

The *treatment* of an attack of biliary colic is best effected by the hypodermic injection of morphine in sufficient quantity to allay the pain (gr. $\frac{1}{4}$ to $\frac{1}{2}$). Hot fomentations, if they can be borne, may be applied to the seat of pain.

After the attack, the patient should be warned against the use of purgative medicines. The bowels should be regulated by diet, and the use of some simple laxatives if required. The diet should be regulated, especially as to quantity, overloading of the stomach at any meal being prevented; the use of beer and strong wines and hard water should be forbidden; a tumbler of Vichy water (Célestine or Haute-Rive) should be taken twice a day with a table-spoonful of

lemon-juice, and a pill containing $\frac{1}{2}$ grain of pulv. ipecac. prescribed night and morning. The patient should be enjoined to take regular exercise, and tight-lacing should be avoided.

If a gall-stone become impacted in the common duct, and persistent jaundice ensue, ipecacuanha may be given in order to increase the fluidity of the bile, and attempts may be made to dislodge the calculus by the use of duodenal purgatives, calomel (gr. ij to gr. v), or sodium sulphate (3j) (Carlsbad salts)—drugs which cause active peristalsis.

Success may occasionally attend such treatment, but more often the case ends fatally unless relief can be obtained at the hands of the surgeon. Great success has followed the operation of *cholecystotomy*, or opening the gall-bladder, for the removal of calculi. It may be recommended when the gall-bladder can be felt below the costal margin, and when there are urgent symptoms pointing to the presence of a calculus. If there be jaundice, the indications for the operation are not so clear, as the calculus has certainly passed beyond the cystic duct, but in some cases it has been found possible to press it back again into the gall-bladder, or to crush it *in situ* and remove the fragments through the opening in the gall-bladder. Another objection to the operation where jaundice is present arises from the fact that such cases are often complicated by cancer of the gall-bladder. It is, however, quite justifiable to determine this fact in doubtful cases by laparotomy.

ROBERT SAUNDBY.

GARGLES are liquids used for local application to the fauces. A small quantity—about a table-spoonful—is taken into the mouth, and, the head being thrown well back, the fluid is agitated by means of the air expelled from the larynx, so as to bring it into contact with the mucous membrane around. Many persons cannot permit the fluid to go beyond the uvula without immediately swallowing it. The use of sprays and lozenges, or brushing the throat with an astringent solution, is rapidly superseding the gargle in the direct treatment of affections of the fauces.

GASTRIC FEVER.—This is a popular term which has not any precise scientific meaning. It is used indiscriminately by the laity for any febrile ailment of a not very transient character

in which abdominal symptoms are prominent. In a good many instances the malady is enteric fever; in not a few it is tuberculosis; whilst in many cases it is a condition of catarrh or febricula not coming under any of the well-recognized visceral disorders.

GENERAL PARALYSIS OF THE INSANE (General Paresis; Paralytic Dementia; Paretic Dementia).—A disease of the nervous system especially affecting the brain, characterized clinically by progressive loss of power and sensation, and by mental deterioration, tending invariably to dementia, though often for a time presenting exaltation and expansive ideas, almost invariably fatal, and generally presenting post-mortem evidence of organic changes in the brain and its tunics.

General paralysis may be divided into three stages—(1) a period of mental alienation, associated with fibrillar tremblings, chiefly noticeable in the tongue and facial muscles; (2) a period of chronic mental failure and bodily decay; (3) a stage of complete mental ruin, in which the patient is fatuous, and exhibits entire failure of the bodily functions—motor, sensory and nutritive.

The first stage is by some divided so as to make a prodromic or incubative period, but for all practical purposes the division into three stages is sufficient. Many cases, however, diverge very markedly from this arrangement, as in some the motor signs are for a time in abeyance, whilst in others they appear before the characteristic mental failure. The essential feature of the disease is a progressive decay of both the mental and bodily powers.

First Stage.—During the early period of this stage there is often considerable difficulty in deciding as to the nature of the disease, there being generally some alteration in the moral nature before the friends notice any bodily defect, so that a gradual alteration of character may take place, and may lead the patient into legal difficulties, and render him liable to prosecution for such criminal acts as incendiarism or rape, or cause him to become the prey of designing persons, before the insanity is recognized. The principal mental symptoms to be noticed at this period are alterations in demeanour, conduct, temper, and disposition; enfeeblement of memory and loss of power in the highest acquirements, especially if the latter be of a

nature demanding much skill and originality; childishness and emotional display; excessive sexual desire, often accompanied by loss of power; lascivious acts, untruthfulness, stealing (often without any attempt at concealment); mental depression, with some consciousness of impending failure of powers, or a gay, hilarious, reckless, expansive feeling of well-being, with benevolence.

With these symptoms great changeability and inability to fix the attention are often associated. Insomnia is common, or there may be excessive drowsiness at unusual times of the day. Acts of violence may occur, or a fortune may be squandered, or the patient may enter into schemes which lead to his own ruin and that of others.

The principal bodily symptoms and signs in the early period are some defect of sight, hearing, or smell, which may exist long before the disease declares itself; headache, a feeling of confusion in the head, neuralgia, and diminished cutaneous sensibility. Occasionally there is ocular paralysis, and the pupils are frequently irregular or minutely contracted. Fibrillar tremors of the tongue and lips are often present, especially when the patient attempts to speak. Feebleness of gait may be noticed, whilst in some cases definite locomotor ataxy precedes for a long period the mental symptoms. The handwriting in the early period is characterized by the omission of terminal letters or syllables, the repetition of words, careless or untidy penmanship, or perhaps actual shakiness in the formation of letters; but in some cases the handwriting of a naturally careless penman will improve from the fact that he becomes conscious of the necessity for effort in writing. The speech may be hesitating, or slow and monotonous; words may be omitted or repeated. Occasionally retention or incontinence of urine or fæces occurs early in the attack. Finally, the occurrence of epileptiform or apoplectiform seizures may be the first symptom to call attention to the disease.

The early phenomena may pass imperceptibly into a definite mental alienation characterizing the first stage, or there may be some acute mental disturbance marking its distinct onset.

Any clinical form of mental disturbance may occur, so that the onset may be maniacal, melancholic, stuporous, or of the nature of dementia, the physical signs in some cases not being manifested for many months. If the onset be mani-

acal, the attack may be attended by all the violence, sleeplessness, destructiveness, and mental confusion of a severe attack of acute mania, but with this there will be associated delusions of an ambitious or expansive nature.

Delirium of exaltation, in which the patient has exaggerated ideas of his wealth, strength, position, and powers (sexual and otherwise), often of the most extravagant nature, but varying from day to day, and being always confused and contradictory, in contrast to the fixed ideas of grandeur in some cases of monomania, is a very frequent and most important symptom. Formerly this kind of delirium was looked upon as a *sine quâ non* for the diagnosis of general paralysis, but it is now well recognized that many cases commence with, or are characterized principally by, depression. This may vary from hypochondriacal delusions, such as that the bodily organs are lost, rotten, or obstructed, or that the patient is dead (necromimesis), to melancholic sadness with hallucinations of a persecutory nature. Food may be refused, and there may be a suicidal tendency, or even a condition resembling melancholia with stupor. According to Mickle, "melancholia, when it occurs as a temporary phase, is associated rather with the commencement of the disease, hypochondria with the middle part of its course, though each may be found in any part."

If the attack be characterized by dementia at the onset, the symptoms are more likely to be a gradual loss of memory (first affecting that for recent events), of reason, and will-power, with failure of the moral faculties, and perhaps slight temporary excitement or extravagance, and a sense of well-being. Incontinence of urine and fæces are apt to occur.

Whatever be the form of onset, dementia is the natural tendency of the disease, and therefore, even in the melancholic form, loss of memory and dirty habits are likely to occur with much greater certainty and frequency than in ordinary melancholia. In rare cases, attacks of excitement and depression alternate, the disease being then known as *general paralysis of the double form*.

The characteristic motor signs of general paralysis may be masked at the onset by maniacal excitement or stupor, or may not be exhibited till long after the mental symptoms. When present, however, some or other of the following will be found: An increase of the difficulty

of speech, which may occur very early in the attack, and is principally noticeable in the attempt to articulate words containing many consonants or many syllables, some of which are frequently omitted. There may also be stoppage or stuttering, or great effort to get words out, associated with marked twitching of the lips or face.

In the expansive and maniacal forms there will frequently be great loquacity, but amnesia is most often seen in the variety commencing with dementia. The affection of speech is always more marked as the patient becomes fatigued with talking. The tongue is protruded with difficulty, or jerked out, and is often rested on the lower lip as if for support, and shows marked fibrillar tremors. Sucking or swallowing or masticatory movements are of common occurrence. There is usually a loss of expression in the lower part of the face, the lines becoming smoothed out. The occipitofrontalis muscle, however, is frequently observed to be contracted so as to produce an aspect of surprise, or the expression of different parts of the face may vary so as to give an incongruous effect.

There is impairment in manual dexterity, the writing showing a similar condition to the speech—namely, omission of words and syllables—or the result may be a confused jumble of inconsequent sentences. Moreover, in the patient's letters obscene remarks or allusions to his wealth or powers are frequently found. The grasp of the hands becomes feeble, or perhaps unequal and tremulous. The gait may be ataxic, with absence of the knee-jerks, or spastic, with exaggerated reflexes, or else simply awkward, clumsy and tottering, with a tendency to trip against obstacles. Occasionally the knee-jerks are different on the two sides. Apoplectiform or epileptiform fits may occur, but are not so common as in the later stages of the disease.

The pupils may be equal, and react to light normally, but in a large number of cases they are unequal in size or irregular in shape, and sluggish in reaction to light, or they may exhibit extreme contraction. In ataxic cases the typical Argyll-Robertson pupil is frequently found.

The skin is generally coarse, greasy, or muddy-looking; in some cases there is great pallor, in others a florid condition of the cheeks; sudden flushings of the head and face may occur, and there may be herpetic or other eruptions.

With regard to sensory symptoms, there may be defect of colour-sense or defective vision; the latter is sometimes associated with atrophy of the optic discs. There may also be hallucinations of any one or of all the senses. The muscular sense is perverted, giving rise to feelings of increased size (megalo-manie) or shrinking (micromanie). Voisin insisted on early loss of the sense of smell, especially for pepper, as an important symptom, but this has not been corroborated by other observers. There is sometimes cutaneous hyperæsthesia, but more frequently a general dulling of sensibility. Occasionally *hæmatoma auris* is met with.

At the end of the first stage a remission may in some cases make its appearance and last for months, the mental health being apparently almost normal or exhibiting merely slight feebleness. Remissions are of varying degrees of completeness, and are generally associated with obesity.

In the **Second Stage** of the disease the physical signs become more marked and the speech more and more incomprehensible. The tongue, perhaps, cannot be protruded at all, or only for a moment. The appetite may be voracious, and the manner of eating gross and gluttonous; mastication is imperfect, and deglutition may be almost impossible from anæsthesia of the pharynx, the result being that food passes into the larynx. The face becomes more expressionless, the gait feebler, and the action of the hands still more impaired.

The general condition of the patient becomes worse. Having been perhaps unduly fat towards the end of the first stage, or after the cessation of the initial excitement, or during a remission, he now wastes again, and becomes cachectic. He may bruise easily, or suffer from *hæmatoma auris*, or be subject to abscesses of large size, or to carbuncles. Hæmaturia, melæna, and diarrhœa are all at times met with.

Epileptiform, apoplectiform, or paralytic seizures are now more apt to make their appearance, and in one of them death may occur. Varying degrees of paralysis, from slightly increased weakness of one arm or leg to definite hemiplegia or to general flaccidity of the limbs, are associated with these attacks, which are usually accompanied by a marked rise of temperature. The paralysis may be temporary or permanent, or end in coma. Consciousness may be retained during the fit. The patient

now leads a merely vegetative existence; he has to be washed, dressed, and fed like a child, and, if he be an inmate of an asylum, his dirty habits prevent him from associating with any but those suffering in a similar way. Bed-sores may form if not carefully guarded against, and there is a tendency to gangrene, resulting from the low state of the general nutrition.

The mental condition in this stage is one of marked dementia, the memory being almost entirely gone, and the patient utterly unable to care for himself; but even the most demented cases may still chatter vaguely about "millions" when their speech is almost incomprehensible, and there may be a constant restlessness, leading them to destroy their clothing or bedding. In some cases markedly hypochondriacal ideas are present.

There is in this stage great diminution of visual and auditory power and failure of common sensibility, pain being apparently only slightly felt. Patients in this state will, however, occasionally present for a few hours an amelioration of their condition, there being a temporary recovery of memory and other powers.

In the **Third Stage** the extreme of mental and physical deterioration is reached. The patient is bedridden, cannot stand or do anything for himself, flexion of the limbs with rigidity makes its appearance, the reflexes, superficial and deep, tend to disappear, the mouth opens mechanically at the approach of a spoon or any other object, and there is constant dribbling of urine and incontinence of feces. The patient grinds his teeth, he may never attempt to speak, his limbs waste, he may suffer from bed-sores, and, if not carried off in a fit, he may die of some lung, intestinal, or bladder complication, or from simple exhaustion. The bones are frequently extremely brittle from diminution of the earthy constituent and increase of fatty material, and hence fracture of the ribs may easily occur from any slight violence, and perhaps give rise to pyæmia or pleural inflammation.

Duration.—Severe acute cases may end in death in a few weeks; the average duration of most cases, however, from the time of recognition of the disease is, roughly, between two and three years. If, however, all the so-called prodromal symptoms be included as a part of the attack, the average duration will be found to be longer. Some cases last as

long as ten or fifteen years, but this prolonged duration is very rare. The average duration is longer in females than in males, in quiet demented cases than in those with excitement, and in those with hereditary tendency than in those without.

Diagnosis.—General paralysis in its onset is frequently overlooked; the moral perversions, though noticed, are not considered sufficient evidence of the presence of disease. A change of character in a man of middle life, especially if he has been an active, hard-working individual, should always excite the suspicion that general paralysis is impending, but the diagnosis cannot positively be made till the onset of the characteristic symptoms.

From ordinary acute mania or other forms of insanity the diagnosis is often difficult in the early stages, but is made certain by the occurrence of motor symptoms. In senile cases there is a resemblance in some respects to ordinary senile dementia, as in both there may be croticism, extravagance, loss of memory, and fits, but in the latter there is but little tendency to generalized paresis. Localized paralyses or hemiplegia are of more common occurrence.

Acute mania from alcoholic excess may resemble general paralysis at the onset, especially if associated with exaltation and tremors. Time alone will show the real nature of the case.

Syphilitic disease of the brain or meninges may simulate the demented form of general paralysis. In the former the cranial nerves are more often affected, and optic neuritis or other signs of localized disease may be present, whilst the characteristic affection of the tongue and lips is wanting. There are cases, however, of general paralysis in which the onset of the disease has been preceded by signs of cerebral syphilis with local palsies, and in which it would appear that syphilis has really acted as a cause.

From monomania of grandeur, general paralysis is diagnosed by the affection of speech and other motor symptoms, by the more changeable nature of the exaltation, and by the course of the disease.

Intra-cranial tumours sometimes give rise to symptoms simulating the demented form of this disease.

Further, it may be mentioned that disseminated sclerosis, dementia associated with hemiplegia or other paralyses and paralysis agitans may possibly be confused with general paralysis.

True epilepsy is said to be never fol-

lowed by general paralysis; but the onset of the latter disease is frequently marked by an epileptiform seizure, or there may be a series of these, so that for a time the diagnosis from epilepsy may be uncertain. The occurrence of the characteristic motor signs will decide the question. Epileptiform attacks occurring in the course of this disease are frequently associated with a rise of temperature.

Plumbism and the excessive use of the bromides may also give rise to conditions simulating general paralysis.

Prognosis.—General paralysis ends almost invariably in death, but some cases, according to Mickle, pass into a chronic weak-minded condition with arrest of the characteristic motor signs of the disease. Finally, a few cases have been recorded in which the patient recovered and remained well for years; in some of these the improvement dated from the supervention in the course of the disease of local inflammations, acute febrile disorders or injuries.

Pathology.—General paralysis may be regarded as the result of over-activity of the nervous system. This, in the first place, usually induces hyperæmia of the cerebral cortex, followed by exudation from the vessels, degeneration of the nervous elements, and their replacement by embryonic or connective tissue. There is considerable difference of opinion as to whether the disease should be regarded as of an inflammatory or degenerative nature, but the two processes go on concurrently, and are probably to a great degree mutually dependent. In rare cases the disease commences in the spinal cord, with symptoms either of locomotor ataxy or lateral sclerosis, and the brain appears to be secondarily affected; but, however it may begin, the whole of the nervous system eventually becomes involved.

Morbid Anatomy.—The most common changes are—(1) thickening of the dura mater, with perhaps evidence of hæmorrhagic pachymeningitis and opacities of the arachnoid. The latter appearance is generally present in advanced cases, and with it there is excess of sub-arachnoid fluid from wasting of the subjacent convolutions, hyperæmia, and thickening of the pia mater, which, in the great majority of cases, is adherent in scattered patches to the summits of the convolutions, the cortex being often torn in the attempt to peel off the membrane. (2) The cerebral cortex is irregularly wasted, and presents areas of hyperæmia or anæmia. The

atrophy is chiefly noticeable in the frontal and parietal regions, where in places the grey matter may be almost indistinguishable. (3) The interior of the brain may show alteration of consistence, either in the form of induration or softening. The ventricles are frequently much distended, and the ependyma covered with minute pearly granulations. The ganglia at the base are usually somewhat softened or wasted. The cerebellum also is generally somewhat soft. (4) In the spinal canal, meningeal changes may be found similar to those in the skull, and small calcareous plates are occasionally seen upon the arachnoid. The cord is often very soft or atrophied; but, on the other hand, definite sclerosis may be found in either the posterior or lateral columns, or in both. The grey matter is frequently diminished in quantity and pale in colour, or there may be local wastings. The nerves of special sense and the spinal nerves may also show atrophy. (5) The blood-vessels may present atheromatous or syphilitic changes, and hæmorrhage into the brain is occasionally met with. *Microscopically*, there are found distortions, thickening, and distension of blood-vessels, with proliferation of the nuclei, especially of the outer coat, and increase in size of the perivascular spaces, with exudation of leucocytes. In the vessel walls there are frequently molecular or pigmentary deposits. The neuroglia is found to be thickened and hypertrophied—changes leading to the formation of patches of sclerosis. The nerve cells show granular fatty, or pigmentary degeneration; they are altered in shape, and have lost their processes and undergone atrophy. Similar appearances are often found in the spinal cord.

Etiology.—One cause alone is rarely sufficient to give rise to general paralysis, there being almost invariably a combination of several. The following are the most important:—

(1) Sex. The disease is about four times as common in males as in females. (2) Age. The disease is most common between the ages of thirty and fifty-five years, the period of life most subjected to severe strain, although cases have been reported at the early age of fifteen, and also when the patient was over seventy. (3) Heredity is a predisposing cause in some cases, but in a less proportion than in other forms of insanity, and would appear to be a more frequent factor in females than in males. (4) The great majority of general paralytics

are married. (5) Occupations or conditions of life involving great physical or mental strain and emotional disturbance with insufficient rest for repair. The lower classes are more frequently affected than the upper. Pecuniary difficulties and other adverse circumstances are frequent and potent factors in the ætiology of the disease. (6) Intemperance in drink. (7) Sexual excess, which, although considered by some authorities to be almost the sole cause, probably rarely acts alone, and cases are frequently seen in which the complete absence of this cause can be established. Sexual excess as a symptom in the early stage may be mistaken for a cause. (8) In some cases general paralysis has followed directly upon an injury to the head; while, in others, an injury has appeared to act merely as a predisposing cause. (9) Syphilis. (10) Lead poisoning. (11) Excess in the use of tobacco has been considered as the exciting cause in some cases.

Treatment.—The disease is practically incurable when once the characteristic symptoms have developed. In the very earliest stage, when the patient is conscious of an impending break-down, a complete cessation from all causes of emotional or mental strain might act beneficially, but he is usually regarded as hypochondriacal by his friends, and, instead of rest, an attempt is made to stimulate him into cheerfulness. In most cases the patient is, however, unconscious of his condition, and will not allow that he needs rest. Hence, almost invariably removal to an asylum is sooner or later necessary. No drugs appear to have any effect in cutting short the disease. In syphilitic cases, however, appropriate remedies should be tried, although the results are not encouraging. In some cases a remission or arrest of the symptoms has followed the occurrence of an injury or a local inflammation, or the application of iodine to the spine. General paralytics are very susceptible to powerful drugs, and such should be used with great caution. The question of return to home when a remission occurs can only be decided by a full consideration of each individual case. Some have so complete an arrest of symptoms that it is difficult to retain them in an asylum as persons of unsound mind, but a return to home life frequently accelerates the final break-down, especially if followed by attempts at sexual intercourse or indulgence in any form of excess. R. PERCY SMITH.

GLANDERS (Farcy).—An infectious disease, of rare occurrence in man, and derived almost invariably by direct contagion from the horse, but capable of transference from one human being to another.

The virus of the disease may be received by inoculation through a cut or an open sore, or upon a mucous membrane. The period of incubation is short, lasting as a rule not more than four days.

Symptoms.—If there be a wound, it soon becomes inflamed, its edges puffy and surrounded by an erythematous blush, and there is a purulent discharge. The lymphatics in the neighbourhood become red and tender, and the glands enlarged. When the lymphatics are cord-like and nodulated (farcy buds), the disease is called farcy, but the two diseases are really identical. Languor and headache, aching pains in the limbs, nausea and vomiting, high fever, a frequent pulse, a dry skin, constipation followed by diarrhœa with fœtid motions, are the chief symptoms in the early stage. Generally within a week of the onset of the disease bright red points or papules, surrounded by a yellowish or erysipelatous blush, appear on the face, nose, cheeks, or about the joints. These are soon converted into flat vesicles or bullæ, varying from $\frac{1}{4}$ to $\frac{1}{2}$ inch in diameter. They become depressed in the centre, soften, and form abscesses, which burst, giving exit to a thick sanious pus, and leaving unhealthy-looking ulcers with everted edges.

An important, though not an early or constant, symptom is the presence of a viscid discharge from the nostrils, streaked with blood. The nose becomes blocked with crusts, and is swollen externally; necrosis of the septum often results, the discharge being then purulent and offensive. The patient generally has cough, with blood-stained sputa. Rigors are not uncommon, and delirium and coma usher in a fatal termination.

The disease may occur in an acute or a chronic form. In the acute form it is very fatal, death usually occurring within two weeks, and often much sooner. In the chronic form the symptoms are similar, but are evolved more slowly. The patient becomes emaciated and cachectic, and may die in the course of three or four months, or he may ultimately recover after a protracted and tedious illness.

Ætiology and Pathology.—There are

good grounds for the belief that glanders is due to the presence of a micro-organism. A bacillus, about the size of the tubercle bacillus, but thicker and mobile, has been discovered in the nodules of equine and human glanders, and it has also been proved that the inoculation of horses, rabbits, and guinea-pigs with the cultivation products is followed by the development of a disease presenting ulcers and nodules similar to those occurring in glanders, and that the bacillus is present in the blood, urine and organs of the inoculated animals.

Morbid Anatomy.—After death, nodules, hard or purulent, according to the stage of the disease, may be found in the lungs, liver, spleen, and in the brain and its membranes. The joints often contain pus; the bones also may be affected. Hæmorrhagic abscesses are often found in the muscles of the limbs, abdominal walls, and intercostals, a condition which has been regarded as characteristic of the disease.

Treatment.—If the patient be seen sufficiently early, it would be proper to cut out or destroy with caustics the wound through which the inoculation took place. Abscesses should be freely drained as soon as possible, under antiseptic precautions. Antiseptic remedies, such as quinine or mercury, may be given internally, and a liberal supply of stimulants with a nourishing diet.

JOHN ABERCROMBIE.

GLANDULAR HYPERTROPHY.—This term is used when a lymph gland is found to be enlarged and no direct cause for the enlargement can be assigned. When glands have been inflamed and remain enlarged for long periods without undergoing much alteration, they are sometimes spoken of as being in a condition of "simple hypertrophy." It is possible that lymph glands may undergo a true physiological hypertrophy from having an unusual amount of work to do, as the converse atrophy from disuse is known to occur both as a senile change and as the result of the removal of the tributary lymphatic area—for example, the amputation of an arm or a leg.

In lymphadenoma, the axillary or femoral glands undergo hypertrophy; in one form of leucocythæmia, and in some forms of lymphosarcoma, if a gland be excised and examined, sometimes only a simple increase in the normal constituents is found, and it is to the enlargement of the lymph glands found in these diseases that

the term hypertrophy is most often applied. There can be little doubt, however, that in the subjects of these diseases there is some general constitutional change, although the nature of it is at present undetermined. The state of the glands in the above-mentioned diseases will be found described under the appropriate headings (*see* LYMPHADENOMA; LEUCOCYTHÆMIA; LYMPHOSARCOMA; *also*, LYMPHATIC SYSTEM, DISEASES OF).

FRANCIS G. PENROSE.

GLOBUS.—The sensation of a ball rising in the throat, a symptom commonly complained of by hysterical women.

GLOSSO-PHARYNGEAL NERVE, Diseases of the.—This nerve supplies motor branches to the stylo-pharyngeus muscle and to the middle constrictor of the pharynx, but it does not supply—at any rate in the monkey—the levator palati, as that muscle receives its motor supply from the accessory nerve to the vagus. The glosso-pharyngeal is also the nerve of taste for the posterior part of the tongue and the soft palate, and it also supplies sensory nerves to those parts and to the upper portion of the pharynx.

Symptoms.—Paralysis due to disease of the nerve itself is of very rare occurrence. It may result from syphilis, meningitis or diphtheria. The symptoms are loss of taste at the back part of the tongue, and some difficulty in swallowing, with anæsthesia about the fauces. The nucleus of the glosso-pharyngeal nerve can hardly be diseased without the vagus, spinal accessory, and hypoglossal nuclei being also involved. In bulbar paralysis the motor part only of the glosso-pharyngeal nucleus is, as a rule, affected, along with the other motor nuclei (*see* BULBAR PARALYSIS). It is often difficult to separate the symptoms due to paralysis of the glosso-pharyngeal nucleus from those resulting from the destruction of the other nuclei.

Treatment.—No special treatment need be described, as the diseases of which this affection forms a part are discussed in detail under their respective headings.

C. E. BEEVOR.

GLYCOSURIA.—A condition in which grape-sugar is present in the urine.

Other forms of sugar are occasionally observed. Lactose has been detected in the urine of nursing women, and levulose and inosite or muscle-sugar sometimes occur, but for the recognition of these

forms the sugar must be first separated from the urine; the ordinary tests do not distinguish these bodies from grape-sugar, and for practical purposes this is unnecessary.

Detection of Sugar in the Urine.—Grape-sugar has the power, in the presence of an alkali, of reducing solutions of several metallic salts, so as to throw down an insoluble sub-oxide of the metal or even the metal itself. This reaction is made use of clinically for the detection of grape-sugar.

(1) *Trommer's Test.*—To a quantity of urine a few drops of a solution of copper sulphate are added, and afterwards an excess of liquor potassæ. The mixture is then boiled, and the presence of sugar is shown by the precipitation of a red sub-oxide of copper.

Fallacies of Trommer's Test.—The liquor potassæ may on boiling cause the urine to become of a very dark colour, so that the precipitation of the sub-oxide of copper cannot be seen. If too much copper sulphate be used, the addition of the liquor potassæ causes the deposit of black oxide of copper when no sugar is present, and so invalidates the test. For these reasons it is desirable to have the proper proportions of alkali and copper already prepared in a test solution.

(2) *Fehling's Test.*—Fehling's solution, which meets the necessity just referred to, has the following composition:—Crystallized sulphate of copper 34.64 grms., tartrate of soda and potash 173 grms., solution of caustic soda (sp. gr. 1.12) 480 c.c., water sufficient to make 1000 c.c. Of this solution a quantity is taken sufficient to form a column nearly an inch in height in a test-tube. This must now be boiled before urine is mixed with it. The test solution is prone to decompose on keeping, and then when boiled will deposit the sub-oxide of copper before the addition of the urine. If the solution remain clear on boiling, a few drops of the suspected urine are added to it, when, if a large amount of sugar be present, the mixture becomes of a yellow colour, and in a short time deposits the sub-oxide of copper as a yellow or red precipitate. If no change be observed, more urine must be poured in, but never so much as to exceed the amount of test solution employed. The mixture is again heated until it just boils, but no longer, and is then allowed to cool slowly. If sugar be present, the sub-oxide is thrown down as a yellow or red deposit, or, if there be only a small

amount of sugar, merely a greenish milkiness is produced.

Fallacies of Fehling's Test.—Sir William Roberts has pointed out that it is essential that the test should be performed exactly in this manner to avoid several sources of error. His work on Renal Diseases may be consulted for details. It need only be stated here that an excess of sugar will prevent the precipitation of the sub-oxide; that the alkali of the test precipitates the earthy phosphates from the urine, and these may be confused with the sub-oxide; that uric acid and other substances reduce the copper solution, even if no sugar be present; and that all these fallacies are avoided if the test be performed with strict attention to details.

The liability of Fehling's solution to decompose may be obviated to a great extent by keeping the copper sulphate and the alkali in separate solutions of due strength, to be mixed in equal quantities at the time of testing, or by enclosing the solid ingredients in india-rubber or the fluid in glass capsules.

(3) *Pavy's Test.*—Dr. Pavy's ammoniacal copper solution, depending upon the same reaction, is employed in the same manner. In the opinion of the writer it is more useful for quantitative testing, and its composition and uses are given later in this article in the description of the mode of estimating the amount of sugar in the urine.

(4) *Mulder's Test.*—A solution of the sulph-indigotate of soda is added to the urine, and the mixture rendered alkaline by carbonate of sodium. The whole is then boiled, and, if sugar be present, the blue colour of the indigo is changed to a pale yellow. This is due to the reducing action of the sugar upon the indigo-blue, changing it to indigo-white. On standing for some time, and especially if shaken in contact with the air, the blue colour again returns.

The special recommendation of this test is that it can be rendered portable in the form of the test-papers introduced by Dr. Oliver. Separate portions of bibulous paper are soaked in solutions of sulph-indigotate of soda and of carbonate of soda, and afterwards dried. One of each of these papers is placed in a test-tube with a little water, and a blue solution is obtained. To this a drop of urine is added, and the mixture boiled. If sugar be present, the blue colour is gradually changed into a yellowish tint, passing through shades of red and violet.

(5) *The Picric Acid Test.*—A solution of picric acid, boiled with liquor potassæ in the presence of grape-sugar, is reduced to picramic acid, and the yellow colour of the original solution is changed to a deep red. This test has been introduced by Dr. George Johnson for the detection of grape-sugar in urine.

A small quantity of a saturated solution of picric acid is placed in a test-tube, and an equal part of liquor potassæ is added. About the same quantity of the urine to be tested is poured into the mixture, and the whole is boiled. A deep-red colour indicates the presence of sugar.

(6) *Phenylhydrazin Test.*—Phenylhydrazin has the power of forming with grape-sugar a yellowish crystalline compound, with difficulty soluble in water, and called phenylglukosazon. This reaction is made use of for the detection of sugar in urine, and has been specially recommended by von Jaksch.

Two parts of phenylhydrazin and three parts of acetate of soda are placed in a test-tube, which is then half filled with water. The test substances may be conveniently measured by the amount which will lie upon the point of an ordinary penknife. The solution is slightly warmed, and the urine to be examined is added until the tube is full. It is now placed in a vessel of boiling water for fifteen to twenty minutes, and afterwards allowed to cool by standing in a beaker of cold water.

If much sugar be present in the urine, a yellow crystalline precipitate forms at once, and under the microscope is seen to consist of yellow needles. If only a small quantity of sugar be present, it is well to place the mixture in a conical glass, and examine microscopically the yellow deposit which may form. The test is not interfered with by the presence of albumen.

(7) *Moore's Test.*—This, which is one of the older tests, is not to be recommended, as it is not sufficiently delicate, and is also very liable to fallacies. The urine is boiled with an equal quantity of liquor potassæ, when, if sugar be present, the fluid will assume a dark-brown tint.

Fallacies of Moore's Test.—Many urines which do not contain sugar give a brown coloration with liquor potassæ when boiled, and this is especially the case when, as often happens, the liquor potassæ has absorbed lead from the bottles in which it has been kept.

(8) *The Fermentation Test* is not suffi-

ciently delicate for qualitative testing, though in a modified form it may be made use of with advantage for estimating sugar (see under *Volumetric Methods*). There are certain other tests known, such as the bismuth test, the naphthol and thymol tests, the acetate of lead test, and the diazo reactions, which are not to be recommended for clinical purposes, by reason either of their extreme liability to fallacies or to their being too complicated for easy application.

Estimation of the Amount of Sugar in the Urine.—A rough idea of the quantity of sugar in a diabetic urine may be obtained from the density of the urine—the higher the density, the greater the amount of sugar present. This rule, however, can only apply when large quantities of urine are passed and the secretion resembles a solution of grape-sugar in water. A specific gravity of 1030 and upwards should then excite the suspicion that sugar is present. It has been pointed out by Sir William Roberts that the relation between the density and the quantity of sugar is by no means constant in urine in which the natural ingredients are present in greater proportion than normal, as is the case when only a small quantity is being excreted. Even for clinical purposes more accurate methods are required, and of these the following may be specially mentioned:—

(1) **Volumetric Methods.**—Three methods are made use of for estimating the quantity of sugar volumetrically.

(a) *Fehling's Method.*—The composition of Fehling's solution has already been given. Ten cubic centimetres of the solution contain as much copper as is reduced by 0.05 gm. of grape-sugar. Of the urine to be examined 10 c.c. are placed in a burette and diluted with water to 100 c.c. Ten cubic centimetres of Fehling's solution are placed in an evaporating dish, diluted with about twice or thrice the volume of water, and boiled. The diluted urine is then added to the diluted Fehling's solution drop by drop, and the fluid is boiled and stirred after each addition. This is done until all the blue colour is discharged from the copper solution, when the number of cubic centimetres of urine which have been added is read off from the burette. To determine more accurately the end point of the reaction, when the suspected stage is reached some of the test fluid may be filtered. A portion of the filtrate is acidified with acetic acid, and a solution of ferrocyanide of potassium added. A brown precipitate indicates that copper

is still present, and that not enough urine has been used. On the other hand, if to another portion of the filtrate a few drops of Fehling's solution be added, and a precipitate of oxide of copper obtained on boiling, too much urine has been used. In either case the estimation must be repeated from the beginning.

The quantity of Fehling's solution originally employed represents 0.05 gm. of sugar in the urine used to reduce it. The number of c.c. drawn off from the burette, when divided by 10, gives the quantity of urine taken, since this was diluted ten times. The percentage of sugar in the urine will be obtained by multiplying 0.05 by 100 and dividing by the number of cubic centimetres of urine used. Thus, if 12 c.c. of diluted urine were used, this would represent 1.2 c.c. of the original urine, which would contain 0.05 gm. of sugar. The percentage would be obtained from the proportion—

$$1.2 : 0.05 :: 100 : x \therefore x = \frac{100 \times 0.05}{1.2} = 4.16$$

(b) *Pavy's Method.*—The end point of the reaction with Fehling's solution is difficult to determine, by reason of the precipitated oxide of copper interfering with an observation of the colour of the solution. Dr. Pavy has therefore suggested the employment of an ammoniated copper solution wherein the ammonia retains the copper oxide in solution after reduction has taken place. The blue colour of the solution is discharged by sugar, but no precipitation of copper oxide takes place. This solution also is much more stable than Fehling's solution. Pavy's solution is made thus:—Copper sulphate 4.158 grms., tartrate of soda and potash 20.4 grms., caustic potash 20.4 grms., strong ammonia (sp. gr. 0.88) 300 c.c., water to 1000 c.c. Of this solution 10 c.c. are decolorized by 0.005 gm. of sugar. The solution is made by dissolving the tartrate of soda and potash in one portion of water, and the sulphate of copper in another portion. The solution of sulphate of copper is poured into that of the potash salts, the ammonia is added, and the whole diluted with the required amount of water.

The solution can be carried in glass tubes, each containing 10 c.c. The solid materials for the test may also be carried in the form of pellets, one containing caustic potash, another the copper sulphate and tartrate of potash, together with ammonium chloride. The pellets are dissolved separately, and the solu-

tions when mixed represent 10 c.c. of the test solution.

Into a small flask are placed 10 c.c. of the solution diluted with 20 c.c. of water. A burette is filled with the urine to be examined, diluted to 1 in 20. The burette and flask are to be connected, so that air is excluded from the flask, and now the test solution is heated to boiling. The urine is run into it drop by drop until the whole of the blue colour is discharged. The number of cubic centimetres of the diluted urine used divided by 20 gives the number of cubic centimetres of the original urine containing 0.005 grm. of sugar. The reason for excluding air from the flask is that the solution, when decolorized, rapidly absorbs oxygen from the air and resumes its blue colour.

In Dr. Pavy's original paper (*Lancet*, vol. i. 1884, p. 376)—which may be consulted for further details—a table is given of the amount of sugar per 1000, corresponding to the different number of cubic centimetres of urine employed.

(c) *Johnson's Method*.—Dr. George Johnson has applied his picric acid test for sugar to the volumetric estimation of sugar in urine.

By the action of sugar in the presence of liquor potassæ, a yellow solution of picric acid is reduced to a red solution of picramic acid, and the depth of the red colour produced can be made a measure of the amount of sugar present in the urine. A standard solution of picramic acid is required, with the colour of which the results of the reaction can be compared. This, it is found, may conveniently be such as would correspond to $\frac{1}{4}$ grain of sugar to the ounce of urine. The colour of picramic acid, however, rapidly changes on exposure to light; therefore a solution of acetate of iron is employed equal in colour to the standard picramic acid solution, and made according to the following formula:—Liq. ferri perchlor. fort. (sp. gr. 1.338) 1 drachm; liq. ammon. acetat. (sp. gr. 1.017) 4 drachms; glacial acetic acid (sp. gr. 1.065) 4 drachms; liq. ammoniæ (sp. gr. 0.959) 1 drachm; distilled water to 4 ounces. The urine to be examined is diluted to five or ten times its volume. A drachm of the diluted urine is boiled for sixty seconds with 30 minims of liq. potassæ and 40 minims of concentrated solution of picric acid, sufficient water being added to make 4 drachms of the solution. After boiling, the solution should, if necessary, be diluted with water to make its volume again equal to 4 drachms. The boiling

is best performed in a long test-tube marked at the height of 4 drachms.

The deep-red solution must now be diluted until its colour exactly equals that of the standard solution. This is done in a stoppered tube 12 inches long and $\frac{3}{4}$ inch in diameter, graduated into tenths and one-hundredths; attached to it is a smaller tube containing the test solution. The boiled mixture of urine and test is poured into the larger tube up to the height of one of the tenth divisions, and it is then diluted with distilled water until its depth of colour is exactly equal to that of the test solution. The number of degrees of dilution is then read off.

During the boiling the 1 drachm of urine taken was diluted to 4 drachms; consequently, if the diluted solution after boiling had equalled in colour the test solution, the original urine would have contained 1 grain of sugar to the ounce. If further dilution were required to bring it to this standard, say from ten to thirty-five divisions, 3.5 grains of sugar to the ounce would be indicated. But at the beginning the urine was diluted, say, ten times. Therefore the result above obtained must be multiplied by 10 to give the amount of sugar present in the original urine. A fuller account will be found in Dr. George Johnson's work on "Albumen and Sugar Testing."

(2) *Differential Density Method*.—

When yeast is added to a urine containing sugar, fermentation is set up, and, as the result of the destruction of the sugar and the production of alcohol, the urine loses in specific gravity. Sir William Roberts has based on this phenomenon a method of estimating the amount of sugar in a urine by comparing the specific gravity before, with that after fermentation. He has shown that every degree of specific gravity lost in the process corresponds to 1 grain of sugar per ounce in the urine examined, and, by means of a urinometer with a sufficiently lengthy stem, a difference of half or even a quarter of a degree may be noted.

About 4 ounces of the saccharine urine are put into a 12-ounce bottle, and a lump of German yeast about the size of a cob-nut or small walnut is added to it. The bottle is closed with a nicked cork, to allow of the escape of carbonic acid, and put in a warm place to ferment. Beside it is placed, for comparison, a tightly corked 4-ounce bottle filled with the same urine, without yeast. At the end of twenty-four hours the specific gravities of the two specimens are taken

and compared, and the "density lost" ascertained. It is well, two or three hours before doing this, to remove the urines to a cool place, so that they may attain the same temperature as the atmosphere.

The percentage of sugar in the urine may be obtained by multiplying the number of degrees of density lost by 0.23. This method is very accurate, easily carried out, and, although a delay of twenty-four hours is required before the result can be known, the actual time consumed in the necessary operations is very little.

(3) **Polarimetric Method**—Glucose turns the plane of polarized light to the right, and, if a urine containing this sugar be examined by the polariscope, the number of degrees through which the polarized beam is diverted may be taken as a measure of the amount of sugar present. The instruments used for this method of estimation are those of Mitscherlich, Soleil, or Rothe.

The determination is, in practised hands, very rapidly performed, but it is liable to fallacies. Levulose occurs sometimes together with glucose in pathological urines, and in diabetic urines β -oxybutyric acid is frequently found. Both these bodies turn the plane of polarized light to the left, in the opposite direction to glucose, and so neutralize, to a certain extent, the action of the latter. The delicacy of this method is greatly increased by estimating the polariscopic deviation before and after fermentation, as recommended by Hoppe-Seyler and others. The necessary instrument is expensive, and the operator must be expert in its use, so that this method is scarcely adapted for clinical purposes.

Symptomatology.—It has been shown that sugar may be found, albeit in extremely small quantities, in most normal urines. It may occur in larger amounts as a temporary constituent of the urine in a great variety of conditions. The urine of nursing women, especially, when after the child is weaned, the secretion of milk continues plentiful, has been found to contain lactose, and the urine of the sucking child occasionally contains the same substance. In the course of certain of the specific fevers, in asphyxia, after poisoning by morphine, curare, carbonic oxide, nitrite of amyl, and other compounds, and in the course of heart, lung, and kidney diseases, sugar may appear in the urine.

In connection with some affections of

the nervous system, such as epileptic attacks, concussion of the brain, cerebral hæmorrhage or tumour, especially when these lesions have been situated in the neighbourhood of the fourth ventricle, glycosuria has been noted as a transient phenomenon.

In all these conditions, however, the glycosuria is only temporary, yet there are other cases in which sugar may be a permanent constituent of the urine, and yet the general health may be scarcely, if at all, affected. Such a simple glycosuria is prone to occur in persons beyond middle age who partake freely of sugar or amylaceous substances; also in the obese and in those of gouty tendencies. The condition has been noted in connection with constitutional syphilis, and Dr. Ord has described its occurrence together with attacks of angina pectoris. Moreover, in a certain number of cases, it appears to be hereditary. There may accompany the glycosuria some degree of polyuria, a little thirst and some muscular weakness, and the liver too may present a notable enlargement, but not uncommonly all these symptoms are absent. The wasting and other signs of true diabetes do not occur; the affection may last for years without causing more than very slight distress to its subject, and is not, in itself, dangerous to life.

The *pathology* of glycosuria has necessarily been discussed in treating of diabetes mellitus. In most of such cases as are referred to here, the glycosuria is probably due to the sugar from the intestine escaping detention in the liver and transformation into glycogen. Such escape may be caused by so copious an ingestion of sugar-forming substances that the liver is incapable of dealing with them. But in some cases no such error of dietetics can be traced. There the liver, or possibly one of the other glyco-genic tissues, is in fault. Dr. Ord has suggested that high arterial tension in one part of the body may be compensated for by a dilatation of vessels in some other part, say in the liver, and that thus glycosuria may be induced. This would explain the occasional association of glycosuria with angina pectoris and granular kidney.

Treatment.—If the condition be slight, no treatment whatever is needed. If more pronounced, and the patient be at all distressed by thirst, the adoption of a not too rigorous diabetic diet, as already described, and with this the administration of alkalies and salicylate

of soda, will suffice to keep the disorder in check. (See DIABETES MELLITUS.)

ROBERT MAGUIRE.

GONORRHOEA IN THE FEMALE consists chiefly in an acute vaginitis, but the urethra is generally also inflamed.

Symptoms.—The disease is marked by a copious discharge of pus, and by injection of the vagina, which is especially noticeable on the tops of the rugæ, where there may be slight erosions. It is not possible, from the evidence of the unaided senses, to distinguish vaginitis of gonorrhœal origin from vaginitis not so caused. We can only judge by the greater severity and the suddenness of origin of the gonorrhœal inflammation.

Complications and Sequelæ.—The inflammation may spread down the ducts of Bartholin's glands, and produce supuration of these glands, a labial abscess, or, short of this, the inflammation may persist in the ducts, the openings of which will be seen to be reddened, and out of them pus can be squeezed. The treatment of this complication is to pass a fine director (a lachrymal director will answer the purpose) down the duct, and slit it up, and then cauterize the exposed surface with nitrate of silver.

The inflammation may spread to the cervix uteri, and cause cervical endometritis; or, further, to the body of the uterus, and thence along the Fallopian tube to the peritoneum. It may thus cause peri-oophoritis, or even abscess of the ovary. The salpingitis may be suppurative, and the pus may escape into the peritoneum through the tube, and peritonitis, first local, then general, may follow; or the tube may become distended with pus, its end having been closed by inflammation. The tube may ulcerate through or burst, and peritonitis be set up. The pus may, however, be retained for months or years, and undergo inspissation. In that case the disease will be the cause of persistent suffering, and a source of danger. The pain may diminish in time, but the affection can only be cured by the removal of the diseased tube.

If the vaginitis be left untreated, or be improperly treated, chronic leucorrhœa may last for years, just as a gleet does in the male sex. How long it remains infectious has not been determined.

The urethritis may lead to stricture, as it does in the male, but this is not a frequent consequence in the female;

or the inflammation may spread to the bladder, and cystitis be the result.

Gonorrhœa, when very acute, and the patient leading an active life, may lead to bubo—*i.e.*, inflammation and possibly supuration of the inguinal glands.

It must not be forgotten that a woman may have a discharge which, although not gonorrhœal, may cause urethritis in the male.

Pathology.—Recent investigations have gone far towards showing that gonorrhœa is due to a specific organism, the "gonococcus"; but the difficulty in distinguishing this coccus from others is so great that our knowledge of this microbe cannot yet be said to have reached the stage of clinical utility.

The treatment consists in rest in bed, the administration of laxatives, the avoidance of alcohol, and the frequent use of mild astringent injections, such as chloride of zinc gr. $\frac{1}{2}$ -j ad $\overline{3j}$, or tannic acid gr. iiij-vj ad $\overline{3j}$, or corrosive sublimate i in 1000 or i in 2000. Weak injections, frequently repeated, answer better than strong injections given at longer intervals; but if the patient cannot be persuaded to use the mild injections often enough, stronger may be prescribed. Before the astringent fluid is used, clean water should be injected to wash away the discharge present in the canal. If the patient will submit to thorough treatment the disease can generally be cured in about six weeks. But as, when limited to the vagina, it causes only slight inconvenience to the patient, it is too often the case that she either does not seek treatment, or will not submit to the restraint and trouble which thorough treatment involves; and, therefore, the secondary results of imperfectly cured gonorrhœa are far from uncommon.

G. E. HERMAN.

GOUT (Podagra, affecting the foot; Cheiragra, the hand; Gonagra, the knee).—The word "gout" is derived from the Latin *gutta*, a drop, from the ancient belief that the malady depended on a poison which distilled drop by drop into the diseased joints.

Gout is a constitutional disease, hereditary or acquired, apparently dependent upon an excessive production and accumulation of uric acid within the system, attended by the deposition of urate of soda in the various fibrous and cartilaginous tissues of the body, but especially within and about the joints, and characterized, in the acuter forms of the malady, by recurrent attacks of articular

inflammation, the smaller joints being primarily and chiefly affected.

Symptoms and Varieties.—Gout may be *regular*—i.e., articular, affecting the joints; or *irregular*, a form which comprises (a) visceral gout, in which symptoms referable to internal organs may develop independently of any joint affection, or appear rapidly upon the sudden subsidence of the joint inflammation—i.e., *retrocedent* gout—or seem, variously grouped, to take the place of what would otherwise have been a normal repetition of the gouty arthritis usual to the patient—i.e., *suppressed* gout; and (b) cutaneous gout, including the several forms of skin disease which are common, and have a special pathological significance, in gouty subjects.

Each of these varieties of gout, regular and irregular, may exist in either an *acute* or in a more or less *chronic* form.

1. **Acute articular gout** is commoner in males than in females, appears usually between thirty and forty years of age, is very rarely experienced before twenty, and then only when the hereditary predisposition is strongly marked. First attacks are rare after fifty, and exceptional after sixty-five years of age.

A first attack is frequently, but not always, preceded by recognizable premonitory symptoms; subsequent attacks, however, are almost invariably ushered in by certain prodromata, such as dyspeptic symptoms, flatulence, heartburn, constipation, or irregular diarrhoea. There may be cardiac oppression or palpitation; attacks of asthma, bronchitis or of sore throat, associated with a peculiar velvety appearance of the faucial mucous membrane. Drowsiness, vertigo, disturbed sleep, irritability of temper, neuralgic pains and cramps, are common prodromal symptoms. The urine often appears unduly concentrated, high-coloured and scanty, depositing lithates on cooling. Sometimes the attack is immediately preceded for a day or two by a feeling of unusual well-being; or occasional twinges of pain may be experienced in some of the smaller joints of the foot or hand.

A few hours after midnight the patient wakes with pain in the ball of one or other great toe. The local inflammation and its attendant pain rapidly increase until the latter becomes excruciating, and is intensely aggravated by the slightest movement. The joint appears swollen, with turgid superficial veins; the surface is hot, deep red in colour, tense and shining.

The general symptoms are in sympathy with the local disorder. Chills or even rigors occur, with more or less pyrexia; the pulse is frequent, the tongue furred, and there is loss of appetite, with thirst and constipation. The urine is scanty, abnormally acid, and throws down an abundance of amorphous urates, although the *absolute* amount of uric acid excreted during the twenty-four hours is below the normal. Sleep is prevented by pain and restlessness, and the temper becomes extremely irritable.

Towards morning—sometimes not until after the midnight following—the more acute symptoms subside. The exquisite tenderness of the inflamed joint gives place to a tolerable sense of aching tension, the skin begins to perspire, the temperature declines, and the patient, more or less exhausted, falls asleep. The joint, though less painful, appears more swollen, and is still red and tender, but its surface is more moist and less shining. The termination of the painful paroxysm may be marked by a critical discharge from the bowels or skin or by a very copious deposit of lithates.

This train of symptoms may be repeated with lessening severity for four or five days, or even for some weeks, and during this time other joints may be similarly attacked, contemporaneously or in succession. Finally, the “fit of gout” comes to an end, leaving the affected joint still swollen, oedematous and tender for a time, and the patient temporarily weakened in proportion to the severity of the attack, but often expressing himself as feeling better than he did before his illness. The articular inflammation, though apparently intense, never runs on to suppuration, and the joint or joints which were affected during the attack appear, after a while, to have completely recovered their normal appearance and mobility.

Very rarely does the first attack of acute articular (acquired) gout in the case of a male begin in any other than the metatarso-phalangeal joint of the great toe, and most commonly in the right foot. But other joints of the feet, and even of the hands, are sometimes the first to suffer; and recent local injury—e.g., a sprain or blow—may determine the primary development of gout in a joint, such as the knee, which usually escapes altogether during the earlier period of this disease. As the joint recovers its normal appearance, the superjacent skin undergoes free desquamation.

The first attack of acute gout is almost invariably followed by others, and that after intervals, the length of which depend mainly on the patient's habits and mode of life, but which tend inevitably to become shorter and shorter. With each successive attack other joints are apt to become implicated, and recurrent inflammations increase the stiffness and enlargement of those articulations which have already suffered upon previous occasions.

The duration of the attacks tends to increase in proportion with their greater frequency, and often the general symptoms grow *pari passu* in severity; while, as a rule, the more frequently any particular joint has suffered, the less acute are the local symptoms which it presents.

The second attack is rarely delayed much more than a year after the first; and though the rate at which the morbid process tends to successively affect the joints and the degree in which they suffer vary greatly in different individuals, the permanent joint-mischief which is established sooner or later gradually and imperceptibly merges into that more or less crippled condition which is conveniently distinguished as—

2. **Chronic Articular Gout.**—As urate of soda is deposited in increasing quantity in and about the affected joints, the articulations appear permanently enlarged, and gradually lose their mobility, while the surrounding ligaments, tendons and fasciæ become stiff, thickened and inflexible; hence the joints appear irregularly bulged and nodulated. The skin covering the joints may appear pallid or livid. Concretions of sodic urate (*chalk-stones*) are deposited, and, ultimately destroying the overlying skin by pressure, are apt to produce unhealthy ulcers, which discharge masses or particles of the salt, sometimes mingled with pus, and exhibit but little tendency to heal. Similar concretions or *tophi* may develop in or upon any cartilage or expanse of fibrous tissue, and are thus commonly observed in the helix of the external ear, about the alæ nasi, and along the edges of the tarsal cartilages, where they may give rise to obstruction of the tear duct, and subsequently to lachrymal fistula.

After the smaller joints of the hands and feet, the ankles, wrists, elbows, knees, shoulders and hips tend to suffer. In severe cases the disease may extend so as to involve all, or almost all, the articulations of the body, finally producing, in conjunction with the infil-

trated bursæ, ligaments, and tendons, an absolute crippling of all locomotive organs, with an appearance of extreme distortion and deformity. The recurrent attacks of localized gouty inflammation are less acute, but pain is rarely or never altogether absent, and is readily aggravated by comparatively trivial causes.

At the same time, the general symptoms of the malady increase in severity and frequency; some of those already mentioned under the head of premonitory symptoms are nearly always present in greater or less degree; the general health suffers in proportion, and the patient becomes flabby and enfeebled. Attacks of asthma or bronchitis are common, and may replace exacerbations of the joint-affection, and signs of cardiac degeneration and of circulatory failure are apt to develop.

The urine becomes abundant, pale and watery, of low specific gravity, and deficient in solids, especially in uric acid, which is now seldom deposited; at the same time albuminuria is apt to make its appearance in small quantity, and to be accompanied with hyaline or waxy casts. As the general health becomes enfeebled, crystals of oxalate of lime also are frequently to be found in the renal secretion. Cystitis, prostatitis, and urethritis are not uncommon; and symptoms dependent on interference with the functions of the brain and nervous system may also be developed. Hæmorrhoids are frequently a source of trouble, and in women menorrhagia may be profuse and may persist long after the normal climacteric age.

3. **Irregular Gout.**—Individuals who possess a gouty heritage frequently exhibit peculiar symptoms or groups of symptoms without suffering from any definite affection of the joints. No disease is more certainly hereditary than gout, and few are more truly atavic in order of succession; thus, the *daughters* of a gouty father may apparently escape; their *sons* are extremely apt to exhibit some manifestations of the disease. And, in a less marked degree, women tend to express in their own persons the gouty diathesis inherited from a paternal grandmother. Symptoms of "irregular" gout are also observable in the acquired form of the disease, and occur either between or in place of the "regular" paroxysms of joint-inflammation.

During infancy a proneness to night terrors, epileptoid attacks, enuresis, constipation or irregular diarrhœa, laryngis-

mus stridulus, bronchial catarrh and various forms of eczematous eruption is often indicative of an inherited gouty tendency. The milk teeth may decay rapidly, and the child exhibit other indications of "delicacy." Adenoid vegetations in the naso-pharynx, with their attendant complications, are far from uncommon.

In adolescents and adults various symptoms indicative of functional derangement of the digestive and respiratory organs, of the circulatory system (*e.g.*, repeated flushings, undue susceptibility to cold, phlebitis, and frequent "dying" of the fingers and toes) and of the brain and nervous system (*e.g.*, headache and sciatica), together with affections of the eye (attacks of "hot eye," scleritis, retinitis, and even of glaucoma), may appear.

The cutaneous manifestations of irregular gout mainly take the form of eczema and psoriasis, or of a condition resembling a combination of the two, and prurigo. An eczematous irritation about the anal and the vulval orifices is far from uncommon in middle-aged and elderly gouty subjects, and is often most distressing. Eczema and psoriasis are very apt to reappear about spring and autumn, and, while suffering from the skin affection, patients are commonly relieved more or less completely from the arthritic and visceral manifestations of gout. Erythema and urticaria are apt to be very readily provoked in some gouty persons.

The diagnosis is usually easy in acute cases. *Acute rheumatism* usually appears for the first time before the age of twenty, and exhibits a more gradual mode of invasion, and a different ætiological history. The size of the joints affected, their being less deeply reddened, the less excruciating pain, the profuse acid sweats, the shifting character of the arthritis, the usually high fever, the appearance of the tongue, the characters presented by the urine, and the liability to cardiac complications are usually obvious points in the differential diagnosis. *Pyæmia*, beginning in the great toe-joint, would be distinguishable by its subsequent course and its peculiar pyrexial range. Sub-acute and chronic articular gout possess a history and causation quite different from *rheumatoid arthritis*, which chiefly affects poor and anæmic women, and usually begins between twenty and forty years of age; all the joints tend to be progressively implicated, but the symptoms are not acute or periodic in

character. Urates are not deposited in the joints or elsewhere, and the urine presents no special peculiarity. Some cases of irregular gout may, however, present great difficulties in diagnosis, and require a careful consideration of possible heredity, with the previous and family histories and habits of the patient, and a minute investigation of the symptoms and progress of the case. Care should be taken not to mistake for gouty gastritis the "gastric crises" which are sometimes observable in the pre-ataxic stage of tabes dorsalis.

Ætiology and Pathology.—Gout has been attributed to a loss of nervous energy, especially in respect of the trophic centres; to congestion of the veins and capillaries; to persistent plethora of the digestive organs, especially of the liver; and to a saturation of the blood and secretions by some specific *materies morbi*.

It is now generally admitted that the disease depends upon a surcharging of the system with some substance or substances resulting from the imperfect oxidation of albumen, and especially of albuminous food-stuffs; and *lithic* or *uric acid* is commonly regarded as the particular *materia peccans*. This, when formed by the liver in excess, appears in the blood as urate of soda; and the deposition of this relatively insoluble salt of uric acid in the various tissues (a process most apt to occur in those tissues, such as cartilage, tendon, and ligament, in which the capillary circulation is naturally feeble), together with its attempted excretion by the various excretories, are believed to evoke the various local changes and the peculiar symptoms which constitute the pathology and the clinical history of gout. In other words, gout expresses the clinical aspect, and *lithiasis*, *lithæmia*, or the *lithic acid diathesis* represents the pathological aspect of the disease.

In order that gout may develop, it is obvious that an amount of uric acid must be formed and retained within the system greatly in excess of that which can be eliminated or destroyed by the normal vital processes. And it is equally plain that this abnormal production of uric acid may be brought about by (1) an excessive ingestion of albuminous food; (2) by lessened oxidation of food-albumen not in itself abnormal in amount; and (3) by excessive ingestion, together with diminished oxidation, of albumen. In practical application to humanity, these may be broadly re-stated as (1) eating too much (of albuminous food); (2) eat-

ing enough, but taking too little fresh air and exercise; and (3) eating too much and not taking sufficient exercise.

Two important conditions—hereditary transmission, already alluded to, and impregnation of the system with lead—act as powerful *predisposing causes*. The influence of a dietary rich in nitrogenous elements, especially such as the coarser fibred and less digestible meats, for example, on the one hand, and of deficient bodily exercise in fresh air on the other, are obvious enough; and both these conditions imply an over-taxation, as well as a neglect to secure the proper performance, of the various excretory organs. Sugary and sugar-forming or starchy foods are prejudicial to the gouty, because, being themselves easily and quickly oxidized, they rob the less readily oxidized albuminoids of the means required for their own complete digestion. Alcohol itself acts in a similar fashion as an inhibitor of tissue change; when combined with, or containing, saccharine matter, as in the heavier malt liquors and the sweeter wines, it is still more detrimental; and the imperfectly fermented wines, like ordinary port and sherry, appear to be specially harmful in this respect.

All causes which provoke dyspepsia in the individual tend to derange the digestive organs, and thus to aggravate the tendency to a production of lithic acid in excess; while the excessive production of the various acids normally formed during the digestive processes tends, by diminishing the normal alkalinity of the blood, both to interfere with the elimination of lithic acid and to favour its deposition within the tissues.

All these influences are aggravated by the ingestion of too little water—a dietetic error specially common amongst those who do not live by the sweat of their brow; for water, in addition to its value for cleansing the inside as effectively as the outside of the body, efficiently promotes tissue-change and waste elimination, and can supply the system with oxygen both directly from its own volume of dissolved air and indirectly by chemical decomposition. Over-fatigue, exposure, exhaustion, imperfect nutrition, and all forms of physical and mental excess act generally by depressing the vito-chemical energies of the system.

Uric acid, when produced in such an excess as to give rise to gout, is found in the blood as urate of soda; and is deposited in the cartilages of joints, both within and between the cells, and in the neighbouring fibrous structures, first as a

syrupy solution, from which acicular crystals of the salt are soon precipitated. Thus, by crystalline accretion arise the uratic infiltrations of the articular cartilages, leading in time to their erosion and destruction; as well as the articular nodulation and enlargement; the thickening and fixation of ligaments, tendons, and fasciæ; the enlargement of bursæ; and the formation of tophi and gouty abscesses and ulcers. The fibrous coats of arteries, from the aorta downwards, the walls of veins, the periosteum of bones, the sheaths of nerves, the membranes of the brain and of the eye, may be similarly affected. The substance of the heart escapes, but that organ may suffer rapid degeneration, owing to an implication of the coronary arteries in the gouty process. In the kidney, crystals of sodic urate appear first within the tubules, forming whitish streaks on section; later, they are deposited in the intertubular tissue, and the irritation provoked by their presence may beget a cirrhotic process, which results in the small, contracted, "gouty" kidney, with a corresponding decadence of functional ability. The liver may undergo a fatty enlargement; and the various mucous membranes and the skin become irritated, congested, and diseased by the presence of a toxic agent which they can but imperfectly eliminate.

During a paroxysm of acute gout, uric acid may be detected in the blood or in the fluid obtained from a blister (provided the latter be not raised in the immediate neighbourhood of an inflamed joint). About mvj of acetic acid are mixed with $\text{ʒ}\text{ij}$ of serum, in a watch-glass; a single thread of linen is immersed in the fluid, and the watch-glass, protected from dust, is set aside in a warm place. In a few hours the serum gelatinizes by evaporation; and the thread, when withdrawn and examined under the microscope, is found to be encrusted with rhombic crystals of uric acid (Garrod).

Crystals of urate of soda have also been discovered in the sputa of gouty bronchitis, and as an efflorescence on the epidermis in cases of gouty eczema and psoriasis.

Treatment.—A consideration of the causation and pathology of gout will indicate the prophylactic treatment—mainly hygienic—applicable to those who inherit the gouty diathesis, and required during the intervals by sufferers from the declared disease. Such persons should correct all indolent and self-indulgent habits; they must avoid an

excess of nitrogenous food, especially the coarser fibred meats, smoked and salted provisions, rich and highly seasoned dishes, pastry, strong wines and beers; and should take but little of sugary and starchy food, and of alcohol in any form.

Plenty of exercise, taken regularly in the open air, but always short of over-fatigue; warm clothing; careful attention to the hygiene of the teeth, skin, and bowels; early hours for rest and rising; thorough ventilation of bed- and sitting-rooms; and the avoidance of every kind of excess are also of great importance. Much can be done in this way to ward off impending attacks and to mitigate their severity, although each individual case necessarily requires special modifications of treatment peculiar to itself.

Dyspeptic symptoms need prompt and careful treatment, and debility will call for tonics, amongst which iron, strychnine, and arsenic in small doses are specially useful, regard being always paid to the presence of the lithæmic diathesis. Many gouty patients are intolerant of quinine.

During an *acute attack* the affected limb should be comfortably raised, and so supported as to be free from pressure, jars, and movement. The inflamed joint may be lightly encased in cotton-wool covered with oiled silk, or in a single thickness of lint saturated with a solution of chloral hydrate (gr. ij to 3j), with or without an equal amount of morphine, or equal parts of the liniments of opium, belladonna, chloroform, and aconite, to which in the later stages potassium iodide (gr. v-x) or potassium chlorate may be added with advantage. Treating the joints to a local vapour bath is often specially grateful in the initial stage of inflammation. Gentle friction with a lanoline ointment containing chloral hydrate gr. ij and pot. iod. gr. x to the ounce relieves the troublesome itching which commonly attends desquamation, and promotes absorption. If the kidneys be sound, and especially if there be indications of hepatic congestion, 3 or 4 grains of calomel, followed by an aperient saline draught, is a useful commencement of medicinal treatment. An alkaline mixture containing gr. xv-xx of the citrate of potassium, and the same quantity of ammonium chloride if there be symptoms of hepatic derangement, may be taken every four or six hours; and if the heart be sound and vigorous, a full dose of colchicum (℥xxx of the wine) may be added to

each dose, but this drug must not be given in routine fashion; its effects should be carefully watched and the dose gradually diminished as the acute symptoms subside.

A regular and efficient action of the bowels must be maintained, preferably by the use of saline aperients, or with the aid of a pill containing rhubarb, podophyllin, colocynth and hyoscyamus, together with small doses of calomel or of grey powder in certain cases.

Efficient perspiration should be encouraged by diaphoretics, such as the liq. ammon. acetatis, if necessary. Enfeebled cardiac action indicates the employment of strychnine or strophanthus, with ether and ammonium carbonate, together with lithia rather than potassium salts. Pain and sleeplessness may require the administration of hypnotics, such as chloral, potassium or ammonium bromide, and of anodynes, such as pulv. ipecac. co., or of morphine *sub cute*. The abstraction of blood, whether generally or locally, is never admissible in acute gout. Diarrhoea, if present, should not be hastily or completely checked.

As regards *diet*, the patient should be encouraged to drink freely of bland aqueous fluids, such as toast-and-water, barley-water, seltzer, potash, and Apollinaris waters (soda-water and all soda salts are best avoided by the gouty, in view of the relative insolubility of urate of soda). Milk usually agrees well, and may be sipped freely, especially if diluted with barley-water or with one of the mineral waters already mentioned. Should there be a tendency to vomiting, half the volume of plain or of carbonated lime-water may be added to the milk. Patients already enfeebled and exhausted will need a more generous dietary, but it must be light, and easily assimilable: beef-tea, mutton and chicken broth, and plain soups, in which, as in milk, an egg may be beaten up. In some cases of extreme debility small and repeated doses of sound whisky, brandy, or old rum may be given, well diluted. The indication for stimulants may, however, usually be more satisfactorily met by the administration of the sp. æth. sulph. in medicinal doses.

As convalescence advances, white fish, fowl, game, and mutton may be gradually added to the dietary; with perhaps a little spirit, well diluted, or small quantities of a sound light wine, such as hock, Sauterne, or still Moselle; until, with the more or less complete re-

establishment of his health, the patient is able safely to resume some appropriate form of the regimen sketched under the head of prophylactic treatment.

Stiffness or effusion persisting in a joint after the subsidence of other symptoms is best treated locally by gentle friction with some stimulating liniment containing potassium iodide, and by hot salt water douches, with passive motion, massage, and gentle, regular, elastic pressure. It is usually an additional indication for the administration of tonics, especially iron, strychnine, arsenic, and phosphorus, together with gentle hepatic stimulants and aperients—*e.g.*, ammoniac chloride, podophyllin, euonymin, rhubarb, and the like.

The treatment of *chronic gout* is to be conducted on the same general lines, but the potassium salts are particularly valuable. Doubt has lately arisen as to the value of salts of lithia as eliminators of uric acid, but they are extensively used in chronic gout. Small doses of colchicum, taken for some time together, are useful. Guaiacum is sometimes of service, and tonic medicines, such as preparations of bark and iron, are almost always so, and especially if there be oxaluria. Local treatment, including friction and shampooing, may greatly improve the condition of joints not hopelessly disorganized. The long-continued use of certain mineral waters, such as those of Bath, Buxton, Harrogate, Woodhall Spa (the water of which contains 0.75 grain of iodine and 3.5 grains of bromine in each gallon), Dinsdale-on-Tees, Aix-les-Bains, Aix-la-Chapelle, Baden, Contrexeville, Royat, Vichy, Wiesbaden and Wildbad, is often productive of good results, and especially when combined with the valuable hygienic measures to which patients are commonly subjected, and to which they more willingly submit, during a visit to such health resorts. Gouty ulcers and abscesses should not be too actively treated; a simple dressing of lint saturated with a lithium or potassium salt, continuously applied beneath oiled silk, answers best.

The various manifestations of *irregular gout* must, like those complications which are apt to arise in the course of the disease, be treated as affections of the organs specially implicated, due regard being always paid to the underlying gouty diathesis. Acute symptoms referable to the heart or stomach, acute gouty colic and collapse may require a

liberal administration of stimulants and anodynes, with warmth to the surface, and sinapisms over the heart and epigastrium. Gouty bronchitis is much benefited by the inhalation of fumes of nascent chloride of ammonium. Arsenic is not always well borne in the cutaneous affections of the gouty, and such patients appear to be sometimes rendered worse by a too rapid mending of their skin troubles. When flannel is not tolerated in these cases, silk articles of under-clothing are useful substitutes.

Sufferers from all forms of gout derive benefit from residence in a warm, dry, and equable climate. Excessive acidity of the urine, and the deposit of urates from the secretion, are at all times strong indications for the administration of alkaline medicines, with moderate doses of aperients. C. E. SHELLY.

GRANULOMA FUNGOIDES (*Mycosis Fungoides*; *Fibroma Fungoides*). A chronic inflammatory disorder, probably of specific origin, which affects the superficial and deep layers of the skin, and occasionally the mucous membranes. The disease is of rare occurrence in this country, but a considerable number of cases have been recorded in France, Germany, and Italy.

Symptoms.—In the early stages, urticarial, erythematous, or eczematous patches, of irregular shape and size, with well-defined margins, appear on various parts of the body, the scalp and skin of the trunk being perhaps their commonest seats; they are attended by much itching, and are not controlled by ordinary treatment. Exudation may take place from minute fissures, and crusts form over the patches.

Resolution and restoration of the skin to its normal condition may occur at this stage, and serve to clearly distinguish this disease from malignant infiltrations. More frequently, however, the patches become hypertrophic and firm, hard nodules, varying in size from that of a pea to an apple, either sessile or pedunculated, develop on them; frequently, also, large subcutaneous lumps like boils appear and disappear with marvellous rapidity.

Usually the nodular tumours break down and form deep, unsightly ulcers, which contain sensitive, fungating granulation tissue, and discharge thin pus and serum. Considerable pain attends the process, and the patient becomes sleepless and depressed.

Finally, the lymphatic system is af-

fect, and a progressive cachexia is established, which terminates in death, often from pneumonia or pleurisy.

Ætiology and Pathology.—The disease almost always affects adults. Nothing definite is known of its ætiology. It is of variable duration, and generally extends over several years, with periods of temporary improvement succeeded by fresh outbreaks. Microscopically the growths are “granulomata”—i.e., cellular infiltrations of the skin and subcutaneous tissues, closely resembling the lesions of leprosy on the one hand, and small round-celled sarcoma on the other. Many authors attribute it to the presence

of a specific micro-organism, and even claim to have reproduced the disease by inoculation in animals, but recent careful researches have failed to confirm either observation.

Treatment.—In the earlier stages, arsenic, pushed to the most extreme limits, is certainly sometimes beneficial, if not absolutely curative. Pyrogallic acid ointments are the best local application, but their action must be carefully watched. Iodoform is useful for the fungating masses. One case completely recovered after an attack of erysipelas.

H

HÆMACYTOMETER (*αἷμα*, blood; *κύτος*, a cell; and *μέτρον*, a measure).—By means of this instrument it has become possible to estimate approximately the number of corpuscles in a given quantity of blood.

It is obvious that such a numeration could not be made in undiluted blood, and therefore, in every method that has been devised for this purpose, care has been taken to dilute the blood in a certain proportion, the fluid employed being a neutral saline, which does not materially alter the size of the corpuscles. The hæmacytometer usually employed in this country, is that devised by Dr. Gowers (1877). It is a modification of a similar instrument introduced by MM. Hayem and Næchet, the modification mainly consisting in having the micrometer scale engraved on the glass slide instead of being introduced in the eye-piece of the microscope.

The apparatus consists of—(1) A capillary pipette, graduated to 5 c.mm., for receiving the blood when drawn; (2) another pipette graduated to 995 c.mm. for receiving that quantity of the diluting fluid; (3) a small glass vessel in which the two fluids can be thoroughly mixed; and (4) a cell the depth of which is exactly $\frac{1}{10}$ millimetre, and on the floor of which there is graven a micrometer scale in squares of $\frac{1}{10}$ millimetre each. The diluent fluid, as recommended by Dr. Gowers, consists of sulphate of soda 104 grains, acetic acid 1 drachm, and distilled water 4 ounces.

The procedure is very simple. The blood is obtained by puncturing the

finger, which should be previously cleansed, and it is important not to squeeze the finger at all forcibly. The drop of blood is drawn up into the tube (1) until the requisite amount is collected (5 c.mm.). This is then ejected into the vessel (3), which has been previously filled with the measured quantity (995 c.mm.) of the saline solution by means of the graduated pipette (2). Here the blood and saline are thoroughly mixed by means of a small glass spatula. The mixture thus consists of 995 parts of saline and 5 parts of blood or as 200 : 1. A drop of this mixture is then placed in the cell, which is completed by adjusting the cover-glass, and, after a few minutes' interval to allow of the corpuscles being deposited at the bottom of the cell, the numeration is made by counting the corpuscles visible in each square. It is well to count the numbers in at least ten squares, and then to strike the average contents of a single square.

The calculation of the number of corpuscles per cubic millimetre of blood is then easily made by multiplying the number per square by 100,000, or the number in 10 squares by 10,000. For since the cell is $\frac{1}{10}$ millimetre in depth, and each square is $\frac{1}{10}$ millimetre, the corpuscular contents of the fluid contained in the small space represented by a single square must, to be expressed as one cubic millimetre, be multiplied by $(5 \times 5) \times (10 \times 5) = 500$, and this again multiplied by 200 will give the number of corpuscles in that amount of undiluted blood. Thus, supposing the average number of corpuscles per square be 50, the number per cubic millimetre

will be $50 \times 100,000$, or $5,000,000$. By this method also, since the normal average of red corpuscles is $5,000,000$ per c.mm., the percentage composition is obtained by taking the average number contained in two squares. Thus, supposing there were 42 per square, the percentage will be 84.

Such a calculation is of course only approximate, since the normal average contents of the blood in red corpuscles varies, according to sex, age, and other circumstances, both above and below the limit named. The number of white corpuscles may be counted by the same means, but it is necessary in their case to count them in a large number of squares before striking the average, owing to their relatively small numbers. In health, for instance, there would be about one white corpuscle to seven or eight squares.

The red corpuscles are somewhat altered in aspect by admixture with the saline fluid, but they retain their relative size. It will be noticed that their colouring matter tends to accumulate in a little mass in the centre of the corpuscle. The white corpuscles are readily distinguished by their glistening aspect. They are best numerated by using a low power (fifty diameters) and noting how many of the squares are visible in the field, as well as the number of corpuscles. After use it is of the highest importance that each part of the apparatus be thoroughly cleansed.

There is no need to describe other forms of hæmacytometer that have been employed. As stated, that of Hayem and Nachet has the squares contained in a micrometer eye-piece and a cell, to receive the diluted blood on the stage, as in Dr. Gowers' instrument. Malassez, for this latter purpose, used a capillary tube, the capacity of a given length of which was known, fixed in the slide. Zeiss and Thoma have devised a method of varying the amount of dilution of blood, and the graduation of their slide is so planned as to facilitate the counting process, the area of the squares being smaller than in Gowers' instrument. But for clinical purposes, where the instrument is required even more for comparative observations than for absolute estimations, the latter apparatus is excellent, whilst the simplicity of its construction and use are not its least merits.

The purposes to which the hæmacytometer may be put clinically are too obvious to require any detailed description. It enables a more accurate estimation of the relative numbers of the red

and white corpuscles to be made than was hitherto possible. It is of considerable service in estimating the action of hæmatinics; and in the diagnosis of cases of essential anæmia it is often of much value. Since, however, it admits of a certain degree of fallacy, which is quite unavoidable in dealing with such a minimal dilution of the blood, it is of less value in physiological research.

SIDNEY COUPLAND.

HÆMATEMESIS (Vomiting of Blood) is a symptom rather than a disease, and occurs in a variety of pathological conditions. These may be divided broadly into two classes—the *general*, or constitutional, and the *local*.

The former class includes various febrile diseases, such as yellow fever and small-pox, also scurvy, anæmia, leucocythæmia, and purpura hæmorrhagica. Hæmatemesis takes place in the various forms of irritant poisoning, and is alleged to be sometimes vicarious of menstruation.

In the latter class a sub-division must be made according as the stomach is or is not the seat of organic disease. Simple ulcer and cancer of the stomach on the one hand, and venous obstruction from hepatic or cardiac disease on the other, form the chief varieties here. Fatal hæmorrhage occasionally occurs from rupture of one of the circle of veins which surrounds the lower end of the œsophagus; and in rare cases, fatal from hæmatemesis of gastric origin, no lesion has been found in the stomach. Blood coming from the posterior nares, or from the lungs during an attack of hæmoptysis, may be swallowed unconsciously and brought up by vomiting, and an aortic aneurysm may perforate the œsophagus or stomach and give rise to profuse hæmatemesis. Malingerers sometimes swallow blood intentionally and bring it up by vomiting.

Symptomatology.—Hæmatemesis is preceded by pallor, giddiness, and a feeling of nausea and faintness. Sometimes actual fainting occurs. Vomiting then ensues, and upon the quantity and quality of the blood brought up the diagnosis largely depends.

Hæmatemesis is remarkable on account of its profuseness in two classes of cases chiefly—namely, in simple gastric ulcer, and in portal congestion due to cirrhosis of the liver. In cancer, on the other hand, the bleeding is usually comparatively small in quantity. The blood oozes slowly into the stomach, and is

acted on by the gastric juice before being vomited, so that it presents a "coffee-ground" appearance. It is difficult to tell sometimes whether such an appearance is due to blood or not; if so, a small quantity of the vomit should be placed in a test-tube and treated with tincture of guaiacum and ozonic ether, when, if blood be present, the characteristic reaction will be observed.

Diagnosis.—Difficulty is sometimes experienced in making the diagnosis between hæmatemesis and hæmoptysis, especially when the vomited blood is not seen. The history of the case will help to a certain extent, but the points chiefly to be relied on are these:—In hæmatemesis, giddiness and nausea are more likely to be felt, inasmuch as a considerable quantity of blood may escape into the stomach before vomiting occurs. Vomited blood is darker in colour, and may be mixed with particles of food. It consists partly of clots, and has an acid reaction. In hæmoptysis, the blood is generally brought up after a sensation of tickling in the throat; it is usually in smaller quantities and is ejected with each act of coughing. It is brighter in colour, alkaline in reaction, and frothy from admixture with air.

It must not be forgotten, however, that when a large quantity of blood is vomited some may find its way into the air passages and excite coughing; and, conversely, if coughed up in the first instance, a portion may be swallowed, and may be brought up by vomiting. In such cases, unless the attack is actually seen, the previous history and the state in which we find the patient must be relied on to guide us. *Melæna* (blackness of the motions) is also almost certain to occur after hæmorrhage into the stomach, some of the blood passing down the intestinal tract, and being so acted on by the digestive fluids as to produce the so-called "tarry" dejections. But here again a source of fallacy arises from the fact that after a profuse hæmoptysis it is by no means uncommon for blood swallowed during the attack to be subsequently passed in the motions.

Pathology and Morbid Anatomy.—In cases of the general class, the hæmorrhage has its origin in the altered state of the blood, and probably also to some extent in weakening of the walls of the vessels. In cancer there is an oozing, generally moderate in amount, from the surface of the new growth. In the case of portal obstruction and obstruction from cardiac disease, the blood-pressure

becomes too great for the capillaries to withstand, and transudation of blood takes place. Hæmorrhagic erosions of the mucous membrane may also be found, and are especially frequent in cases of valvular disease. When profuse hæmatemesis occurs in cases of portal obstruction (*e.g.*, from cirrhosis of the liver), the bleeding seems to take place from the whole mucous surface as from a sponge, and no distinctive morbid appearance may be found in the stomach. The bleeding here may be in greater amount than in any other form of hæmatemesis.

In gastric ulcer the bleeding is caused in most cases by the erosion of the wall of an artery.

Prognosis.—This will depend mainly on the cause underlying the hæmatemesis. So far as the immediate result is concerned, the larger the hæmorrhage the greater the danger. The prognosis is not unfavourable in gastric ulcer in the great majority of cases, even where the hæmorrhage is considerable and repeated. In cancer the ultimate prognosis is of course absolutely hopeless. In cases where the hæmatemesis is due to hepatic cirrhosis the bleeding may be so profuse as to destroy life very quickly; indeed, this is the variety of hæmatemesis in which the immediate danger may be greatest. If, however, the bleeding be moderate in quantity, it may, by relieving the portal congestion, be beneficial rather than otherwise. As regards the other morbid conditions giving rise to hæmatemesis, the prognosis is ruled by the nature of the primary disease.

Treatment.—The patient must be placed in the recumbent position, kept perfectly quiet and cool, and given ice to suck. Nothing else should be taken by the mouth in the first instance. The external application of ice to the epigastrium is also to be recommended. If there be reason to suppose that portal obstruction is the cause of the hæmorrhage, the bowels should be opened by laxatives. If, on the other hand, the diagnosis of gastric ulcer or cancer be made, and the bleeding be not arrested by ice, astringents, such as liquid extract of ergot in $\frac{1}{2}$ -drachm doses with 10 grains of gallic acid, should be given every four hours. Opium, also, will be found invaluable; 3 to 4 grains of the pil. plumbi composita of the British Pharmacopœia (acetate of lead and opium) may be given every four hours. If the stomach be too irritable to retain these, the subcutaneous injec-

tion of ergotine (2 to 5 grains) with morphine ($\frac{1}{4}$ to $\frac{1}{2}$ grain) should be employed.

If the case be one of gastric ulcer, absolute rest to the stomach is the most important element of treatment. This is secured by feeding the patient by means of nutrient enemata or suppositories only, for a week or ten days, after which milk, beef-tea, and soups may be given, and a very gradual return to solid diet permitted.

DAVID W. FINLAY.

HÆMATOCELE, PELVIC.—This term, taken in its most comprehensive sense, means an effusion of blood into the pelvis. Some authors speak of *intra-peritoneal* and *extra-peritoneal* hæmatocele according as the blood is effused into the peritoneal cavity or into the cellular tissue outside it. By others, the term *hæmatocele* is restricted to blood effusions into the peritoneal cavity, the term *hæmatoma* being given to bleeding into the cellular tissue. The terms will be thus used here. An intra-peritoneal effusion of blood usually gravitates into Douglas's pouch, and the condition is therefore often spoken of as *retro-uterine hæmatocele*.

Hæmorrhage into the peritoneum may come from many different causes, and is therefore, strictly speaking, only a symptom, or event in the course of different diseases. But as we cannot always find the cause, we are often obliged to treat the condition without regard to its cause.

1. Hæmatocele may arise from *rupture of a vein in the broad ligament*. The hæmorrhage may take place into the cellular tissue of the broad ligament or into the peritoneum. Either form is rare. When it takes place into the peritoneum it is profuse, and rapidly fatal; death has been known to occur in half an hour. The perforation may be due to ulceration, but cases are so rare that nothing can be said as to the cause of rupture beyond what is known of the pathology of venous hæmorrhage in general. Nor are there any definite symptoms preceding the rupture from which its cause may be inferred.

2. *Hæmorrhagic Perimetritis*.—Inflammation of any serous membrane may be accompanied with hæmorrhage, and the peritoneum is no exception to this rule. Cases of the kind have been recorded, but are extremely rare. Slight hæmorrhage from the newly formed vessels of pelvic adhesions are very common, but they are seldom sufficient to attract clinical attention.

3. Hæmatocele may be the result of the *rupture of an ovary*. At every ovulation, rupture of a Graafian vesicle takes place, and is accompanied by an effusion of blood, probably not in health exceeding 5j. Occasionally, when the ovary is enlarged and very vascular, more profuse hæmorrhage occurs. It is probable, but as the cases end in recovery it cannot be proved, that when signs and symptoms of slight hæmatocele follow fatigue, over-exertion, or sexual excitement they may be due to increase of the hæmorrhage normally accompanying the rupture of a Graafian follicle. In other cases, the ovary has been found enlarged, soft, and sponge-like, and infiltrated with blood (resembling the spleen of a subject who had died from purpura or scurvy). Cases of this kind are rare; nothing is known of their pathology, and the few recorded have been rapidly fatal, either from the amount of the bleeding or from subsequent peritonitis.

4. Hæmatocele may be due to *rupture of a Fallopian tube*. The most common cause of this is extra-uterine gestation. There is good reason to think that extra-uterine gestation often terminates in early rupture, followed by absorption of the effused blood and of the products of gestation. In cases that recover, as the diagnosis cannot be verified, we do not know how frequently this is the cause of hæmatocele. But the experience of operators goes to show that extra-uterine gestation is probably the most common cause of hæmatocele. In some cases the tube is found enlarged, thickened, and containing blood, but neither fœtus nor membranes can be found. Such cases may be results of inflammation of the tube (usually bilateral), or they may be pregnancies in which the fœtus has been overlooked, or perhaps has been absorbed.

5. There may be *bleeding from the tubes* into the peritoneum as a result of fevers, phosphorus poisoning, purpura, scurvy, atrophy of the liver and yellow fever.

6. Hæmatocele may follow *delivery or abortion*, but more often the latter. It has been supposed that the blood from the uterus regurgitates through the Fallopian tubes into the peritoneum. It may also, in these circumstances, be secondary to perimetritis. It is probable that many cases which appear to be of this nature are really cases of ruptured extra-uterine gestation in which the supposed abortion was the expulsion of the decidua.

7. Hæmatocele may be a result of

menstrual retention from atresia of the canal. This is the more likely to cause hæmatocele the higher up in the genital canal the obstruction lies. (*See AMENORRHOEA.*)

8. Retention of menses, leading to regurgitation of blood along the tubes, has been attributed to causes other than atresia, some of which are very doubtful—*e.g.*, congenital stenosis of the cervix, hypertrophy or thickening of the cervix, flexions of the uterus, and spasmodic contraction of the uterus. That tumours or cancer of the uterus may block the canal there is no doubt.

9. *Closure of the tubes* at the uterine end, preventing blood exuded by them from escaping *per vias naturales*, may undoubtedly lead to the formation of pelvic hæmatocele.

Symptoms and Signs.—The previous history of a case of hæmatocele will depend upon the condition to which the hæmorrhage is due. The symptoms at the time of the effusion are those of internal hæmorrhage—sudden pain, faintness, pallor. If examined soon after the blood has been poured out, while it is still fluid, no physical signs will be found (beyond those that may have been present before the effusion), or perhaps there may be some slight fulness around and behind the uterus. When the blood has had time to coagulate, and the outer layers of coagulum to become organized and connected with surrounding parts, the physical signs become those of an effusion into the peritoneum. The signs are the same whether the effusion be of inflammatory lymph, of serum, of pus, or of blood. The outline of the swelling felt per vaginam is that of the peritoneum, which forms its lower boundary. A tumour is present which is fixed, dips down lowest behind the uterus, cannot be felt in front of it, and at the sides joins the uterus a little above the level of the internal os, and laterally retreats beyond the reach of the finger in the vagina. If the tumour be large, and the space within which the blood is effused limited by adhesions, the uterus will be displaced forwards. We infer that such an effusion is a hæmatocele when its formation is accompanied by signs and symptoms of internal hæmorrhage (pallor, faintness, &c.) rather than by those of inflammation (febrile disturbance). A large effusion may by its pressure cause disturbance of the surrounding parts; hence irritability of bladder, or retention of urine, rectal tenesmus, and some degree of proctitis are frequently present.

Course and Treatment.—If the patient survive the immediate shock of the hæmorrhage, the usual course of pelvic hæmatocele is to complete recovery by absorption of the effused blood. If the case appear to be following this course, which will be evidenced by the gradual improvement in the patient's condition and progressive diminution in the retro-uterine swelling, no treatment will be called for other than expectant—*i.e.*, rest in bed while there is any pain or fever, tonics if appetite fail, laxatives to prevent disturbance by the passage of hard scybala. But the case may be seen when it does not seem to be tending towards recovery. (1) A case is very seldom seen while hæmorrhage is going on, because, usually, during the time spent in summoning medical aid and in making necessary arrangements, either the hæmorrhage stops or the patient dies. But if a patient be seen in this condition, and it be possible, before she is reduced to a moribund condition, to open the abdomen, it is proper to do so. (2) If a slight hæmatocele be followed by signs of increase, a course which points to the persistence of the condition causing the hæmorrhage, the abdomen should be opened. (3) If the effusion be so great as to cause serious trouble by its size, such as retention of urine or obstruction of the bowel, or if febrile symptoms come on and lead to the inference that suppuration has occurred, laparotomy should be performed in preference to tapping by the vagina. By tapping, fluid is drawn off, but nothing curative is effected; and if the diagnosis be erroneous, tapping may be injurious. If the abdomen be opened, any morbid condition present can be effectively dealt with; and if the operator be competent, the danger is scarcely, if at all, greater than that of tapping by the vagina.

G. E. HERMAN

HÆMATOCOLPOS means retention of blood in the vagina from atresia of that canal (*see AMENORRHOEA*). Beside the usual form, we may have blood retained in one half of a double vagina. In that case we shall find a fluctuating swelling extending down one side of the vagina, and usually on its anterior aspect. As the point of closure may be anywhere in the length of the vagina, the swelling does not always extend down to the vaginal orifice. If the atresia be high up, the blood may be contained in a cavity formed by the vagina and cervix uteri, but it is impossible to say how

much of it is formed by the uterus and how much by the vagina. The *treatment* is to let out the blood by incision, and then cut out a large piece of the septum to prevent it from closing again.

G. E. HERMAN.

HÆMATOMA, PELVIC.—A pelvic hæmatoma is an effusion of blood into the cellular tissue of the pelvis.

In the unimpregnated condition it is rare except as a result of direct violence, or from diseases accompanied by a tendency to hæmorrhage, such as hæmophilia, purpura and scurvy. With these exceptions, it is almost exclusively a disease of pregnancy and the puerperal state. In pregnancy, the veins which return the blood from the genital organs become very large, often varicose, and are liable to rupture either from slight direct violence or as a result of pressure. If this happen, bleeding takes place into the cellular tissue.

If the effusion be slight, so that it does not extend beyond the cellular tissue of the pelvis, it will be distinguished from an intra-peritoneal effusion of blood by being situated at the side of the uterus instead of behind it, and, as a rule, on one side only. The mass which it forms will be in apparent continuity with the uterus as low down as the vaginal insertion, and instead of retreating beyond the reach of the finger, like an intra-peritoneal effusion, it slopes off towards the bony wall of the pelvic outlet. Like an intra-peritoneal swelling, it is fixed, and, like it, as time goes on, gets smaller and harder, and finally disappears. Effusions so small as to be limited to the cellular tissue within the pelvis produce only slight symptoms, which, as to their kind, resemble those of intra-peritoneal hæmatocele, and the case only requires expectant treatment.

In pregnancy or the puerperal state the effusion is seldom limited to the cellular tissue within the pelvis. It usually extends down by the side of the vagina into the labium, where it forms a swelling which may reach the size of a foetal head. The symptoms are mainly those produced by the size and tension of the swelling. The patient will call attention to the swelling, complain of pain in it, and state that both pain and swelling began suddenly. The local troubles are usually more urgent than the general condition. The swelling is tense, at first fluctuating, then of a boggy consistence. It is dark blue or purple in colour, and this, together with its sudden

formation, will distinguish it from an abscess. It is not reducible, by which it is known not to be a hernia. Tumours of the labium will be of still more gradual formation than either of these conditions.

The *treatment* is to keep the patient recumbent, in order to prevent further bleeding, and to relieve pain and prevent inflammation by an evaporating lotion (liq. plumbi subacet. ʒss, spt. vin. rect. ʒss, aq. rosæ Oj). Under this treatment absorption will gradually take place, and as the swelling diminishes, pain will also lessen. Should labour come on, and the swollen labium obstruct the passage of the child, it may be necessary to incise it, or it may burst spontaneously. If either of these events happen, the cavity should be emptied of clot as thoroughly as possible, well washed out with an antiseptic solution (corrosive sublimate 1 in 2000), and a drainage-tube, reaching to its deepest part, inserted. The cavity should afterwards be washed out daily with an unirritating antiseptic, such as a saturated solution of boracic acid. The patient should be kept recumbent until the cavity is nearly filled up.

G. E. HERMAN.

HÆMATOMA AURIS (Bloody Tumour of the Ear.—Insane Ear).—An effusion of blood between the cartilage of the ear and the perichondrium.

Symptoms.—The affection occurs in two forms, the acute and chronic. It begins most commonly in the upper angle of the hollow of the concha, sometimes in the fossa of the helix, and very rarely in the fossa of the antihelix, or in the external auditory meatus. In the acute form a bright red, or bluish-red swelling occurs, and reaches the size of a pigeon's egg in from twelve to forty-eight hours. The tumour is elastic or firm upon palpation, is slightly tender, and generally painless. The absence of tenderness or pain is perhaps mainly due to the mental condition, which is always extremely unfavourable in the subjects of this affection.

In the chronic form the swelling, heat, and injection are much less; the tumour in a few weeks attains the size of a bean and slowly shrivels. In the acute form the tumour, if left to itself, will sometimes suppurate and burst, if blistered it generally shrivels slowly, if incised the same result is more rapidly attained. In any case the result almost invariably is considerable deformity; a hard compact puckered mass, of a dull, dead-white

colour, with tough adherent skin, being left. The pinna loses its form, becoming much distorted and contracted, its graceful curves and hollows disappear, and it remains hard, rigid and resistant.

Pathology and Ætiology.—Hæmatoma auris has been attributed to various causes, to traumatism, degeneration of the aural cartilage, a general condition of the blood, and to local changes in the arterioles. With regard to traumatism, it is a suspicious circumstance that the left ear suffers in the large majority of cases, the left side of the head being that which is most likely to come into contact with the right hand of the attendant, but cases occur quite independent of external violence. In many cases the injury can be traced to the restless habits of the patient. The exact pathology of the affection still remains somewhat doubtful.

Hæmatoma is much commoner among men than women, and is always associated with long-continued excitement and restlessness. In men it occurs most frequently among general paralytics, sometimes in chronic maniacal excitement, rarely in acute mania, active melancholia, chronic epilepsy or terminal dementia. Hæmatoma is usually unilateral, if both ears are attacked there is generally, but not always, an interval, extending from a few days to months or even years. Hæmatoma auris occurs occasionally among the sane, and is then always the result of injury. The writer has seen two cases among football players, and a similar condition is known among pugilists. It is said that a Greek sculptor has represented a boxer with a shrivelled ear. (*Vide* GENERAL PARALYSIS OF THE INSANE.)

Treatment.—In the chronic form a natural cure generally occurs, and this may be hastened by the application of acetum cantharides, or liquor epispasticus. In the acute form the early use of strong lead lotion, or some blistering fluid, often gives a satisfactory result, but multiple punctures, aspiration, or incision are recommended by some writers. The excited condition of the patient, and the probability that any dressing will be promptly removed, render the adoption of these methods undesirable. In the writer's experience early blistering is the best treatment. The blistering agent may be applied to the cranial aspect of the pinna. If incision be preferred, it should be done early, and the ear should be strapped to the head. Considerable

deformity is the usual result of this affection.

GEORGE REVINGTON.

HÆMATOMETRA means retention of blood in the uterine cavity from occlusion of the cervical canal.

It is rare as a congenital condition; its usual causes are cicatrization after injuries in parturition, sloughing, ulcerations, or cauterization.

The *treatment* is to let out the retained blood by an incision through the occluded part, and to keep the canal patent by a stem until the incision has healed (*see* AMENORRHOEA).

Unilateral hæmatometra presents greater difficulty in diagnosis. This term implies that there is retention of blood in one half of a double uterus. The patient may menstruate regularly from the other half, and therefore the guidance given by the symptom of amenorrhœa is wanting, but dysmenorrhœa is usually present. The tumour is formed during menstrual life. It is tense, may fluctuate, and is situated at the side of and close to the uterine canal which is permeable, and which it displaces to the opposite side. It is distinguished from an ovarian tumour by its close adherence to the uterus and its situation low down in the pelvis. In the cases seen by the writer the greater bulk of the tumour has been in front of the open uterus. The natural cure of unilateral hæmatometra by spontaneous opening and discharge of the retained blood is more common than the same occurrence in the ordinary form of hæmatometra. It may also rupture into the peritoneum, or the retained blood may distend the whole tube and escape from it into the peritoneal cavity either by rupture of the tube or through its natural opening. In either case peritonitis is the result.

The *treatment* is to make an opening with the knife, antiseptic precautions being carefully observed, and to keep it open with a glass stem until the margins of the opening have healed. The presence of unilateral hæmatometra does not prevent pregnancy in the naturally developed half of the uterus. It is often associated with absence of the kidney on the malformed side. In very rare cases there may be *retention of blood in an imperfectly developed uterine cornu*, the cavity containing blood being only connected with the cervix uteri by a band of fibro-muscular tissue. It would be scarcely possible to distinguish such a

tumour from an enlarged ovary or a dilated tube. The best treatment would be to remove it by abdominal section.

G. E. HERMAN.

HÆMATOTHORAX.—Hæmorrhage may take place into the pleural cavity under several conditions, of which the following are most frequently met with:—(1) In simple and tubercular pleurisy the fluid occasionally contains blood which has escaped from the newly formed capillary vessels. Blood-stained effusions may also occur in cases of serous effusion in the subjects of scurvy or purpura. (2) Active hæmorrhage may be produced mechanically by direct injury, involving any of the vessels of the lung or chest wall, or of the diaphragm. The rough end of a fractured rib, or a direct stab, or an incautious incision in the operation of thoracentesis may all produce bleeding of this kind. (3) The rupture of an aneurysm of the aorta may fill the pleura with blood. (4) Bleeding may take place from the surface of cancerous or other growths affecting the pleura, or from disintegrating tubercular deposit leading to ulceration.

Treatment.—But little need be said as to the treatment of this condition. In cases of acute pleurisy the diagnosis will only be made when the fluid is being withdrawn, and the treatment of the case will be determined by other considerations. If there be reason to suspect the presence of a malignant growth, it is generally best to leave the case alone. For the treatment of hæmatothorax the result of injury or incised wound, works on surgery should be consulted.

HÆMATURIA.—A condition in which blood is mixed with the urine.

The discovery of red corpuscles is considered a sufficient proof of its existence; if none be present, the term is not applicable. When only the colouring matter of the blood is found in the urine, the term hæmoglobinuria or hæmatinuria is used to designate the condition (see HÆMOGLOBINURIA).

Characters.—The colour varies within wide limits. It depends upon the relative proportions of the blood and urine, on the completeness of the admixture, and on the chemical changes effected thereby. When the blood is derived from the kidney, the intermixing is complete, and the colour of the resulting fluid is sometimes that of pure blood,

but more often a dingy smoky tint prevails, and a red, brownish, or beef-tea coloured sediment is deposited. Sometimes no naked-eye change is perceptible. Every gradation between these types may be found. Blood casts are often present.

When the bladder or the urethra is the source of the blood, it is less intimately mixed with the urine, and retains more of its characteristic appearances. In the former case, the proportion of blood distinctly increases towards the end of micturition. In the latter, it is expelled at the outset and often at the end, as well as—in some cases—in the intervals between the successive repetitions of the act. In both it is frequently clotted. Flat clots come from the bladder; long cylindrical clots in most cases from the ureter. Profuse hæmorrhage is generally due either to tumours or to calculi.

Tests.—The most satisfactory and the most easily applied test is the *microscope*. The red blood discs are easily recognized, though they but rarely retain their normal bi-concave shape. In urine of low specific gravity they become globular, but crescentic or crenated when the specific gravity is high. They are so pale that their colour fails to characterize them. The only objects likely to be mistaken for them are pus corpuscles, which are larger, granular, and easily clarified by acetic acid (see PYURIA); vegetable sporules (*e.g.*, torulæ), which, if not oval and nucleated, have a more highly refracting margin; broken dumb-bell crystals of oxalate of lime, which may generally be identified by the presence of neighbouring uninjured crystals, or the remains of a piece of the connecting bar still adherent to the fragment; and finally the nuclei of renal epithelium. These are recognized, as in the previous case, by fragments of the cell adhering to the nucleus, by the presence in the same specimen of properly formed cells, and by the readiness with which they absorb logwood or methyl aniline staining fluids.

The remaining tests only show the presence of blood-colouring matter, and are therefore equally characteristic of hæmoglobinuria.

(1) Almen's, or the *guaiacum test*, is the one most frequently employed. The reagents needed are the freshly prepared pharmacopœial tincture of guaiacum, and peroxide of hydrogen. The latter is so unstable that a 15 per cent. solution in ether is generally substituted. The solu-

tion is known as "ozonic ether," and, if kept in a properly stoppered bottle, will last some years. Two or three drops of the tincture of guaiacum are added to about a drachm of urine, and the fluid shaken; about twenty drops of ether are then poured upon the top of the mixture. If blood be present, a blue colour appears at the junction of the fluids. This reaction is given by saliva, iodide of potassium, and some other substances when treated in a similar manner, and is therefore, taken by itself, untrustworthy.

(2) *Heller's test* is obtained by boiling urine previously rendered alkaline by liquor potassæ. It consists in the production of a reddish-brown precipitate made up of phosphates and blood-colouring matter.

(3) The *spectroscope* furnishes the most reliable test. The urine, if very dark, should be diluted until it readily transmits light. On placing the glass vessel containing it between the prism and the light, two black bands make their appearance between the D and E lines—i.e., in the yellow and the green parts of the spectrum. These are due to the presence of oxy-hæmoglobin. If this be reduced by the addition of a solution of ammonium sulphide, the two bands are replaced by a single one broader than either, and situated between them. Exposure to the air will re-oxidize the hæmoglobin, and the two bands may again be seen.

(4) Another very reliable test consists in the production of hæmin crystals from the precipitate obtained in Heller's test by drying it on a glass slide, warming with a drop of glacial acetic acid and a fragment of salt, and then setting it aside to cool. It has not much clinical value, as the crystals are somewhat difficult to obtain when only a small quantity of blood is present, and it is much more laborious than any of the preceding tests. In legal cases tests (3) and (4) are essential.

Causation.—The varieties of hæmaturia are generally classified according to the part of the urinary tract whence the blood is derived.

1. **Renal.**—(1) In *congestion* due to a chill or one of the acute fevers the amount is small, the urine slightly smoky, whilst blood casts and other microscopic evidences of the condition are present. Cantharides, turpentine, cubeb, copaiba, potassic nitrate, quinine, and carbolic and hydrochloric acids, in toxic doses, may give rise to hæmaturia. Their irritating effect is

transitory, and is chiefly exerted upon the upper part of the urinary tract. A small amount of blood may also occur in the albuminuria of pregnancy. (2) *Inflammation*.—In acute Bright's disease the amount is variable. Blood casts are generally numerous. In suppurative nephritis and acute pyelitis the amount is small. (3) *Tumour*.—Here the hæmorrhage may be profuse; it frequently depends on some slight injury, and is irregular, both in the duration of the attacks and in the length of the intervening periods. Sometimes clots are formed, in which case renal colic may result. In other cases, especially when the cortex is involved, blood casts may be found. (4) *Tubercle*.—When the disease is primary there may be sufficient blood to tinge the urine, but its presence is often first ascertained during the microscopic examination of the deposit, when thready blood clots and pelvic epithelium may be discovered. (5) *Renal Embolism*.—The quantity is small, the onset and disappearance are sudden, and the duration of the attack is brief. (6) *Calculi*.—Large amounts appear at intervals, especially after trivial injuries, while much smaller quantities, with pus cells, epithelium, and various crystals, are often almost constant. (7) *Parasites*.—In hydatid disease the urine may be tinged with blood. Hæmaturia due to the bilharzia hæmatobium has already been described. (8) *Cystic disease*.—Blood is but rarely found. According to Ebstein, however, its appearance is frequent and intermittent. (9) In hæmaturia of *traumatic* origin suppression of urine often accompanies the condition.

2. **Bladder and Prostate.**—Hæmaturia may be due to (1) *congestion*, (2) *inflammation*, or (3) the presence of a *simple or malignant tumour*. In the latter case the bleeding is generally profuse, and its occurrence intermittent. (4) *Tubercular disease* only occasions hæmorrhage when ulceration is present. (5) *Calculus*. (6) *Parasites*. Hæmaturia due to the bilharzia hæmatobium is mainly of vesical origin. The spiked ova may be found in the blood and mucus passed at the end of micturition. (7) *Ruptured varicose veins*, sometimes known as vesical hæmorrhoids.

3. **Urethra.**—The chief causes of urethral hæmorrhage are—(1) *inflammation and ulceration* as in gonorrhœa; (2) *injury*; and (3) the lodgment of a calculus.

4. **General Diseases.**—(1) *Hæmorrhagic diseases*—e.g., purpura, scurvy,

hæmophilia, leucocythæmia, and pernicious anæmia. In these cases, excepting the last, the blood is generally derived from the pelvis of the kidney or the bladder. Hæmaturia is of rare occurrence in pernicious anæmia, and its cause is doubtful. (2) *Acute specific diseases*—e.g., cholera, yellow fever, remittent and intermittent fevers, and the malignant forms of the exanthemata. (3) A few cases have been described in which asthma, extreme mental emotion, and the malignant forms of the exanthemata, and vicarious menstruation, have been the assigned causes.

5. The possible admixture of blood with the urine after it has left the urethra must not be forgotten. This may occur during menstruation, or in the presence of any vaginal or uterine discharge containing blood. In these cases there is rarely intimate mixing, and normal urine can be withdrawn by the catheter. Suspected malingerers should be made to pass water under observation.

Occasionally, no cause for the hæmaturia can be made out.

Diagnosis.—The principal facts to be determined in any given case are—(1) the colour and the microscopic appearances of the urine; (2) the constancy of the morbid condition; and (3) the degree of admixture.

Prognosis.—This depends on the cause. In those rare cases in which none can be made out the prognosis is generally good.

Treatment.—This again varies with the cause. Where no diagnosis can be made, it may, in the meantime, be necessary to treat the hæmaturia. The only therapeutic measures common to all conditions producing it are—first, absolute rest in bed, and, secondly, relief of the bowels. Cold and astringents are generally recommended, but only when acute inflammatory conditions can be excluded. The cold should be continuous, and should be applied as closely as possible to the supposed source of hæmorrhage. Astringents may be given by the mouth, or may be injected into the bladder. In the first case, gallic acid, ergot, acetate of lead, perchloride of iron, and turpentine have been administered; for the purpose of injection, alum ($\frac{1}{2}$ drachm to a pint of cold water) is almost exclusively employed.

H. MONTAGUE MURRAY.

HÆMOGLOBINOMETER
chæmoglobin; μέτρον, a measure).—It is very important in many cases of

anæmia or other blood disease to know, not merely the amount of red corpuscles in the blood, but the quantity of colouring matter that they contain. For anæmia depends primarily on a deficiency in this constituent, and there are conditions—e.g., chlorosis—where the corpuscular richness may not be much, if at all, below the average, whilst the richness in hæmoglobin may be considerably less than normal.

The simplest and most readily available instrument for clinical use is the hæmoglobinometer, invented by Dr. Gowers (1879). It is intended to give an approximate estimate of the percentage amount of hæmoglobin in the blood, and is based on the comparison of a specimen of diluted blood with a standard mixture of the tint of the same amount of blood diluted with 100 times its volume of distilled water. The apparatus consists of two small tubes of the same calibre—one of which contains the standard (a mixture of glycerin jelly and picro-carmin in such proportion as to give the tint of 20 c.mm. of blood diluted 100 times—i.e., in 2 c.c. of water), the other is graduated in equal parts of 100 divisions in 2 centimetres (100 times 20 c.mm.). Blood to the amount of 20 c.mm. drawn from the finger is received into a fine tube. It is then transferred to the graduated tube, and distilled water is dropped in and thoroughly mixed with the blood by shaking the tube. The colour of the mixture is from time to time compared with the tint of the standard in the other tube, and, when the two approximate, no more water is added. Supposing the standard tint be attained after water has been added to the level of 65 on the graduated tube, then the percentage of hæmoglobin would be 65. It will be found in practice that the tint of the standard is not quite that of diluted blood, owing to the greater opacity of the latter, but the test is sufficiently accurate for comparative observations. Other, but less simple, if more accurate colorimetric methods have been devised by Preyer, Hoppe-Seyler, and Malassez.

SIDNEY COUPLAND.

HÆMOGLOBINURIA (Hæmatinuria) is the term applied to urine containing blood-colouring matter in a form apart from red blood discs.

Characters.—The urine may be clear or turbid, and may vary in colour from a pale pink to a reddish black. Usually it is dark red, and is stated by the patient

to resemble porter or the sediment of beef-tea. On standing, it deposits a still darker sediment, which, when examined under the microscope, is found to consist of dark amorphous granules, with renal casts, apparently composed of similar material. A few red corpuscles may be recognizable. Crystals of hæmin and of oxalate of lime, as well as hyaline casts, are occasionally present. In rare instances the colouring matter takes the form of discs of various sizes. The coagulated albumin is dark, and is often not in larger quantity than may be due to the proteid contained in the red blood discs. Occasionally it is more plentiful, and occasionally also it seems, when coagulated, to show a peculiar tendency to float on the surface of the urine. The specific gravity is generally high, the reaction acid, and the urea liable to considerable variation above or below the normal standard.

Tests.—With the exception of the different microscopic appearances, these correspond to those given under HÆMATURIA.

Classification.—The cases in which hæmoglobinuria occurs fall clinically into two classes. One of these, characterized by recurring periodic attacks, is known as “paroxysmal” or “intermittent” hæmoglobinuria. The other is made up of certain toxic conditions and of certain febrile states in which hæmoglobinuria forms an occasional but prominent symptom.

(1) **Paroxysmal Hæmoglobinuria.**—The immediate antecedent to an attack is usually exposure to cold in a severe or, it may be, only a mild form. In some cases it occurs only in the morning; in others, only in the winter. Exhaustion and malaria are other recognized causes.

Symptoms.—The onset is marked by a sensation of cold, and generally by shivering, as well as by lumbar pain. This is sometimes very intense, extending down the thighs, and accompanied by retraction of the testicles. The extremities become blue and cold, and the temperature rises from two to five degrees. About this time, or during the sensation of heat and the sweating that rapidly follow, the urine is found to be discoloured, and the proportion of corpuscles in the blood is found to have fallen from 2 to 15 per cent. The hæmoglobinuria may persist some hours after the other symptoms have disappeared. Its onset and cessation are quite sudden, and the attack is over in less than twenty-four hours after the first symp-

tom. The destroyed corpuscles are replaced in a few days. Fever of a malarial type is sometimes present, and a yellowish discoloration of the skin, with or without purpuric spots, has been observed in many cases.

Pathology.—In some cases it has been found that the disintegration of corpuscles observed in the urine exists simultaneously in the blood removed by cupping or by puncture, and that the change can be artificially produced in those liable to the condition either by cold or by local interference with the circulation. It would therefore appear that the disease is one of unduly rapid and incomplete blood metabolism, the breaking up of the blood discs occurring in the cyanosed parts. It is uncertain whether the kidneys merely fulfil their ordinary excretory function, or whether, in addition, their vessels are liable to a vaso-motor spasm similar to that affecting the extremities. The association between this condition and Raynaud's disease is so close that many writers regard them as identical; or, in other words, as complementary manifestations of a common process (see RAYNAUD'S DISEASE). Ralfe classes with them a condition in which the symptoms usually associated with hæmoglobinuria are present in a very mild form, and are accompanied by increased discharge of urea and by albuminuria, but not by hæmoglobinuria itself. Many of these attacks were observed in persons who also suffered from hæmoglobinuria. Closely allied to these is pernicious anæmia, in which the hæmolytic action is also increased, and therefore also the urea and urinary pigment.

(2) **Toxic Hæmoglobinuria.**—This condition occurs as an occasional symptom of poisoning by any of the following substances:—Chlorate of potassium (the most frequent); carbolic, hydrochloric, sulphuric, and pyrogallic acids; carbon dioxide; arseniuretted and phosphuretted hydrogen; nitro-benzene; naphthol; mushrooms; also in the following febrile states:—Typhoid fever, scarlatina, septicæmia, and pyæmia. It has been recorded as occurring in an epidemic form among infants; and may appear in cases of burns, fat embolism, purpura, scurvy, and after transfusion of blood from animals of a different species.

Under the following heading both forms of the condition here described are included.

Symptoms.—The only symptoms common to a large number of cases are

rigors, vomiting, and diarrhœa; these are often followed by cyanosis and fatal collapse. In the epidemic form the children became collapsed about the fourth day of life, and died thirty-six hours afterwards. The skin was yellowish, and the superficial veins dark and very visible.

Diagnosis.—If the urine be examined, no mistake is possible. The pain may simulate renal colic, but is bilateral.

Prognosis.—In the first group there is no immediate danger. The occurrence of attacks can generally be prevented by a careful avoidance of the ascertained cause. The cases falling under the "toxic" group are almost invariably fatal.

Pathology.—The kidneys in many cases are of a deep chocolate colour, with radiating striae of a still deeper tint. The tubules contain hæmoglobin. The assumed explanation is a destructive metabolism of the blood.

Treatment.—In the paroxysmal form the diet should consist of hot soups, the clothing should be woollen, and quinine should be administered in large doses. The drug is most efficacious in the cases which most closely resemble ague. During the attack warmth is practically the only remedy. During the intervals protection from all forms of exposure is essential, but especial attention should be paid to the particular cause in each case, as, if this can be avoided, the attacks may often be altogether averted. The patient should, if possible, reside in a warm climate.

H. MONTAGUE MURRAY.

HÆMOPHILIA, or the "hæmorrhagic diathesis," is the term applied to that condition of the body in which there is a great tendency to hæmorrhage, traumatic or spontaneous, and often great difficulty in its arrest.

In the subjects of this remarkable tendency comparatively slight injuries may be followed by serious and even fatal consequences. For example, a slight blow on the surface of the body may produce a large hæmatoma, or the extraction of a tooth may be followed by uncontrollable hæmorrhage. There is also a marked tendency to articular affections, which may take the form of either a simple serous effusion resembling rheumatic synovitis, or a hæmorrhagic effusion, which may be spontaneous, or follow some trifling injury. The effusion, when serous in character, is sometimes excessive in

amount. The knee is the joint most commonly affected. Many cases prove fatal from traumatic hæmorrhage, but in others spontaneous bleeding occurs from the bowels or stomach, or into the brain, and causes death.

The subjects of hæmophilia seldom attain adult life, in spite of the greatest care. Their fatal tendency usually cuts them off in childhood. But cases are recorded which are exceptions to this rule, and it is said that the tendency to bleed is less marked as age advances.

The *pathology* of the condition has been variously interpreted, but it may best be given in the words of Sir W. Jenner, who, in commenting upon a case before the Clinical Society in 1876 (*Lancet*, vol. ii. 1876, p. 718), stated that the points impressed on him by his experience of the disease were:—"(1) That the tissues are all soft, so that they bruise easily. (2) That the blood is rather slow in coagulating, but its coagulum, when formed, is as firm as in health. (3) That blood is formed rapidly; that there is a tendency to plethora of the smaller vessels, and that injuries have the worst effect, and spontaneous hæmorrhages are most likely to arise when the patient is looking his best."

Examination of the blood has not revealed any characters beyond those of marked anæmia, due to the hæmorrhage, so that after death the quantity of blood in the vessels is scanty, pale, and watery. Dr. Percy Kidd has found changes in the smaller vessels, especially the veins (endothelial proliferation and defective formation of the adventitia), and it is highly probable that the cause of the bleeding depends upon such changes in the vessel walls together with the plethoric state.

The conditions found post-mortem include the presence of hæmorrhages in various organs and tissues, especially in sub-serous and sub-mucous tissues, but also in the substance of organs; of hæmorrhages into joints and intermuscular spaces; and the lesions of anæmia, especially fatty degeneration of the heart. Sir W. Jenner states that cardiac malformations are frequently present.

Ætiology.—The tendency first shows itself in early childhood, more particularly at the period of the second dentition. Although preponderating amongst males, females are not wholly exempt from hæmophilia, and beyond puberty they are exposed to the additional risk of menorrhagia, and of flooding after

delivery. *Hæmophilia* is also notable for the manner in which it is transmitted by heredity. Rarely met with in females, it is conveyed through the female line. Thus in a family the sons, or some of them, may be "bleeders," whilst the daughters are quite free from the diathesis. If any of the sons survive and marry, their children may wholly escape; but the male children of the daughters are very likely to be bleeders.

Lossen (cited by Klebs, *Allg. Path.*, Th. i. 1887) gives an example of a family in which three sons were bleeders; one son and two daughters were non-bleeders. One of the hæmophilic sons had two children (son and daughter), neither of whom were hæmophilic; one of the daughters had five sons, all hæmophilic, and three daughters who were non-bleeders. The other daughter had eight hæmophilic sons and four non-hæmophilic daughters, one of whom had a hæmophilic son and two non-hæmophilic daughters. It is noteworthy that in the third generation this was the only hæmophilic out of at least fifty children, showing that the tendency dies out in course of time by marriage with non-hæmophilics.

Colour-blindness and pseudo-hypertrophic muscular paralysis similarly tend to be transmitted to males through the female line.

Treatment.—The prophylactic treatment of hæmophilia rests in the pursuit of a regular life, avoidance of excitement and of excess. To again quote Sir W. Jenner:—"Every month or oftener a mercurial, followed by sulphate of soda, should be administered, in order to control the tendency to plethora. The saline should also be given once every week, and both should be repeated at any time when the patient appears to be fuller of blood than normal. The diet should be rather dry, with a considerable proportion of white meat, and plenty of open-air exercise should be taken. The greatest care should be observed in order to avoid mechanical injuries." For the arrest of external hæmorrhage, strong styptics must be used, the perchloride of iron being the best. The same drug may also be employed in enemata to control rectal bleeding. Ice-bags may be applied to the joints when there is effusion into the synovial cavity. Pressure must be used to arrest the bleeding from cuts; often, however, in spite of every care, the hæmorrhage cannot be checked.

SIDNEY COUPLAND.

HÆMOPTYSIS.—Expectoration of blood may be the result of many different causes, but the term hæmoptysis is usually confined to those cases in which the hæmorrhage takes place from some part of the respiratory tract. Aneurysms of the aorta perforating the lung or large air tubes, and bleeding from the cavity of the mouth or nasopharynx, may give rise to the same symptom, and may thus simulate true hæmoptysis.

Pathology.—If we exclude the slight hæmorrhage which is occasionally seen in connection with blood conditions such as hæmophilia, scurvy, purpura, and certain infectious diseases, in which diapedesis of red corpuscles occurs without gross vascular lesion, it may be said that hæmoptysis is invariably a consequence of the rupture of blood-vessels, and in most cases this depends on morbid conditions of the lungs. Inasmuch as phthisis or chronic tuberculosis is the cause of hæmoptysis in the great majority of instances, we may commence by considering the pathology of pulmonary hæmorrhage in this disease.

The distinction usually drawn between initial hæmoptysis and that which occurs at a later period of the disease is not without value, but, unfortunately, it is not always possible during life to estimate the stage at which phthisis has arrived.

Pulmonary hæmorrhage may be the result of two main conditions—simple congestion, and structural lesions of the blood-vessels of the lung.

Hyperæmia and rupture of capillaries will undoubtedly account for slight hæmoptysis, and this is probably the explanation of many of the minor hæmorrhages met with in phthisis, as well as in bronchitis, emphysema, certain cases of pneumonia, pulmonary embolism, hydatid of the lung, mediastinal tumours of various kinds, cardiac disease, cases of high arterial (aortic) tension, alcoholism, and, perhaps, in vicarious menstruation.

The more profuse attacks of hæmoptysis can hardly be the result of simple congestion, and the explanation of the hæmorrhage must be sought in perforation of some large vessel. This is brought about probably in three different ways. In the first, branches of the pulmonary artery and veins become weakened in consequence of the development of a tuberculous growth in their walls. This change commonly leads to thrombosis and occlusion of the vessel; but softening

and rupture of the vascular wall may also ensue.

The same result may possibly occur in non-tuberculous cases, where the pulmonary artery has undergone atheromatous degeneration.

In a second and commoner form, ulcerative softening of tubercular masses extends to large vessels, and thus gives rise to extensive hæmorrhage. Progressive excavation and gangrenous processes may occasion hæmoptysis in a similar manner in non-tuberculous affections.

A third and far more important vascular lesion consists in the development of aneurysms of branches of the pulmonary artery situated in the walls of cavities. The pathology of these aneurysms is as follows:—The formation of a vomica in the lung, involving a loss of support of the vessels lying on the floor of the cavity, leads to a weakening of their walls on the exposed side. As the result of this change, aided probably by the development of a secondary arteritis, an artery gradually dilates to form a lateral expansion or aneurysm. In the ordinary form, the bulging affects only one side of the vessel; but, occasionally, an artery crossing a cavity becomes uniformly expanded, constituting a fusiform aneurysm. In size, these aneurysms may vary from a pin's head to a plum, though, as a rule, they are not larger than a cherry.

In most cases, a single aneurysm is found, but it is not uncommon to meet with three or four, and in one remarkable instance the writer found as many as twenty-two aneurysms in one lung. Aneurysms are rarely found except in chronic cavities, the vessels becoming more rapidly obliterated when excavation is acute, though exceptions to this rule are not wanting. In a few instances aneurysms of the pulmonary artery have been seen bulging into dilated or ulcerated bronchial tubes. In one case of ulcerative endocarditis in a young woman, affecting both the right and left sides of the heart, the writer found an embolic aneurysm of a secondary branch of the pulmonary artery without any corresponding vomica in the lung. The aneurysm contained laminated thrombus, and had not ruptured. With these exceptions, however, excavation of the lung is an indispensable condition for the development of pulmonary aneurysms, the nature of the disease on which the cavity depends being immaterial.

Aneurysms may undergo thrombosis and

become occluded, or they may rupture and give rise to hæmorrhage.

It is not unusual to find aneurysms completely thrombosed or still patent without any evidence of rupture having occurred. In such cases there is generally considerable thickening of the dilated vascular wall, but where rupture has occurred, thickening, as a rule, is only slight.

Evidence of rupture and subsequent repair is by no means rarely obtained in cases where hæmoptysis has ceased some time before death.

On examining the bodies of persons who have died of hæmoptysis, we find blood in the air passages and pulmonary cavities, and frequently in the stomach also. The lungs are studded with numerous dark-red patches, consisting of blood inhaled into the terminal bronchi and pulmonary lobules. In eighty cases of fatal hæmoptysis examined by the writer a ruptured aneurysm of the pulmonary artery was found in seventy instances.

There appears to be good reason for believing that profuse hæmoptysis, which does not prove fatal, is in most cases the result of pulmonary aneurysm, and in a much smaller number of instances is due to erosion of a large vessel. The same explanation probably holds good for many slight attacks also. The notion that blood effused into the lung may give rise to inflammatory and destructive processes is quite opposed to the results of experiment, and is no longer entertained. The pyrexia which sometimes appears a few days after an attack of hæmoptysis was held to support the view just mentioned; but this is more readily accounted for by the insufflation of infective cavity secretions, together with the effused blood, into distant parts of the lung, giving rise to the development of specific broncho-pneumonic lesions.

Death may in rare cases be due to syncope; but, as a rule, the amount of blood lost is insufficient to account for the fatal termination, which is really suffocative, and depends on the widespread obstruction of the smaller bronchi and air vesicles, caused by the inhaled blood.

Capillary hæmorrhages from the bronchi, trachea, and larynx are not very uncommon, but profuse hæmoptysis depending on affections of these parts is one of the rarest occurrences, and is more likely to result from cancerous or syphilitic ulceration than from tuberculous disease.

In one instance, profuse and fatal

hæmoptysis was found by the writer to be due to perforation of a large pulmonary artery by an ulcer of the bronchus, caused by the pressure of a calcareous bronchial gland. Direct injury to the lung may be mentioned as an occasional cause of hæmoptysis.

Symptomatology.—Hæmoptysis is occasionally preceded by signs of excitement of the circulation, but, as a rule, the attack is quite sudden, and not unfrequently takes place in the night. Exertion and mental agitation appear to precipitate the hæmorrhage in a few instances; more often, however, no exciting cause can be discovered. The quantity of blood expectorated may be very small, or as much as two pints may be lost within a short space of time. The blood is generally bright red and frothy, and is often mixed with sputum. Occasionally it is dark and venous in appearance in cases of profuse hæmorrhage from the pulmonary artery. When bleeding has been going on slowly for some time, the blood collects in pulmonary cavities, and acquires a blackish-red or chocolate colour. Clots are often expectorated, especially as the attack is passing off. The sputum usually remains blood-stained for some days after active bleeding has ceased. A recurrence of hæmorrhage after apparent cure is by no means uncommon. During an attack of hæmoptysis the patient almost always exhibits great apprehension, and feels weak and faint. The face is pale, the extremities cold, the pulse is small and feeble, and blood is brought up at intervals, with a frequent short cough. At times, blood coming from the lung is swallowed and subsequently vomited. The temperature is lowered while the hæmorrhage lasts, but it soon regains its former level, and in some cases a marked rise occurs within the next two to five days. The cause of this febrile movement has already been referred to. Patients are usually much debilitated and depressed after a fit of hæmoptysis, a result which cannot generally be traced to the amount of blood lost, but is attributable rather to the mental shock produced by the attack.

Diagnosis.—The diagnosis of hæmoptysis during the attack presents little difficulty. The expectoration of bright frothy blood and the short frequent cough clearly point to the respiratory organs. In hæmatemesis the blood is dark and grumous, and is often mixed with the contents of the stomach, which give it an acid reaction. Moreover, it is

vomited, not coughed up, and, as a rule, a large quantity is voided at a time, and successive attacks do not occur. In both forms of hæmorrhage, however, blood may be vomited and passed by the bowel, the explanation being that in hæmoptysis the blood has been swallowed during the attack. As long as hæmoptysis continues, and for some little time afterwards, it is better to abstain from physical examination of the chest altogether. At the most we may auscultate the front of the chest without moving the patient, and without requiring him to breathe deeply.

Excluding cases where the disease is advanced, not much information is obtained from superficial examination of the lungs, owing to the presence of blood in the bronchial tubes. Moreover, we not unfrequently fail to discover any definite signs of pulmonary disease on making the most careful examination of persons who have recently had profuse hæmoptysis. This is especially the case where hæmoptysis is the first tangible symptom, the so-called "phthisis ab hæmoptoe." The explanation of this fact is probably to be found in the existence of circumscribed deeply seated tubercular masses, or even small cavities, surrounded by spongy lung tissue, which masks their presence altogether.

The diagnosis of hæmoptysis, so obvious when the attack is actually witnessed, is not always easy when the patient is seen for the first time a week or more after the hæmorrhage has occurred, for here we have to trust largely to the patient's own account of the accident. Careful inquiries should then be directed to the following points:—The nature of the attack, character of the blood, subsequent staining of the sputum, presence or absence of pulmonary symptoms. In most instances the information thus obtained, when combined with a careful examination of the chest, will suffice to settle the question. But in cases with a doubtful history in which physical exploration gives a negative result, and pulmonary symptoms are absent or slight, it may be impossible to determine the origin of the hæmorrhage, especially when the amount of blood lost is small (*see* HÆMATEMESIS).

If the patient be liable to epistaxis, or bleeding from the gums, the difficulty is still greater. In cases of this description the general condition of the patient, the presence or absence of pyrexia and wasting, the family history, and the examination of the sputum for

tubercle bacilli are points which may supply useful information.

When there is reason to suspect that hæmoptysis is false or spurious, the nasopharynx and cavity of the mouth must be carefully inspected, as blood escaping from these parts, especially during sleep, is liable to trickle into the larynx and trachea. Anæmic girls often complain of their mouths being "full of blood" in the morning; others say that they find blood on their pillow on waking. This sometimes appears to be due to oozing from spongy gums, but in other cases the "blood" found on the mouth proves to be simply a brownish deposit on the teeth and gums, representing secretions that have become dried in consequence of the habit such patients often have of sleeping with the mouth open.

In persons with a clear history of syphilis in whom the absence of morbid physical signs and of constitutional symptoms seem to preclude the idea of pulmonary disease, the possibility of syphilitic ulceration of the larynx, trachea, or bronchi should be kept in mind, and careful examination with the laryngoscope must be instituted.

Prognosis.—The prognosis depends not only upon the severity of the hæmorrhage, but also upon the extent of the pulmonary lesion. If there be reason to think that hæmoptysis is due to early phthisis, the patient may be expected to recover from the attack, as death in such circumstances is extremely uncommon. But where confirmed pulmonary disease is present, the possible existence of an aneurysm renders an accurate prognosis impossible, and a guarded opinion should always be expressed. Profuse hæmoptysis is practically always the result of some disease of the lung, and, with rare exceptions, that disease is tuberculous.

Treatment.—In the treatment of hæmoptysis it is important to remember that pulmonary hæmorrhage is the result of two main conditions—hyperæmia and perforation of vessels.

In the first case, the bleeding is seldom profuse, and tends to relieve the morbid state on which it depends.

In the second and more important class, in which life may be directly endangered, the blood comes from vessels, often of considerable size, which have invariably undergone structural changes. The natural method of cure in these cases consists in the formation of a thrombus, sealing up the rent in the artery, or obliterating its lumen altogether. It is

evident, therefore, that reduction of blood-pressure and slowing of the circulation in the pulmonary artery—conditions which favour the establishment of thrombosis—are the principal objects to be aimed at.

The faintness produced by copious hæmorrhage in itself contributes to this end, owing to the depression of the heart's action which accompanies it, and is consequently to be encouraged.

In every case of hæmoptysis, whether profuse or slight, complete rest is of the first importance. The patient must be kept in bed in a cool airy room, and should avoid talking and movement of any kind. Iced milk may be given in small quantities, but no other form of food is to be allowed, and stimulants should be expressly forbidden. Cough may often be relieved by the continuous sucking of small pieces of ice. When hæmoptysis is slight, no further treatment is required. In the case of serious hæmorrhage, the above measures must be supplemented by the administration of suitable drugs. In the selection of these we are met by many difficulties, owing to the fact that remedies like digitalis, which slow the circulation, at the same time raise the blood-pressure. On the other hand, some of the most powerful depressors of arterial tension, *e.g.*, nitrite of amyl and nitroglycerin, cause excitement of the heart's action.

Saline purgatives, which cause determination of blood to the intestine, and thereby lower the blood-pressure, are free from the above objections, and are often of considerable service, though their action is rather slow.

The cough which is excited by the presence of blood in the bronchi is a great source of danger, in consequence of its disturbing effect on the lung. If the sucking of ice fail to give relief to this symptom, opium in some shape is called for. This drug not only gives local rest to the ruptured pulmonary vessels, but it also quiets the restlessness of the patient which is often so pronounced a feature. Moreover, there is some reason to think that opium is possessed of hæmostatic properties. At the same time, death from hæmoptysis being more often due to asphyxia than to loss of blood, it must be allowed that the sedative influence of opium on the respiration may sometimes be injurious.

The hæmostatic action of oil of turpentine and tartar emetic are probably to be attributed to their depressing action on the heart.

Ipecacuanha in nauseating doses, recommended so strongly by Trousseau, induces faintness, and seems to act in a similar manner to turpentine; but its tendency to occasion vomiting constitutes an objection to its use.

Styptic medicines, such as gallic acid, lead and ergot, which are supposed to arrest hæmorrhage by causing vascular contraction, are more generally used than any other remedies at the present day, though the reasons given for their use are not very convincing.

It is difficult to believe that vaso-constrictive drugs can be of service in profuse hæmoptysis depending on perforation of vessels, seeing that in these cases the contractility of the muscular coat must be either abolished or seriously impaired.

On the other hand, the rise of blood-pressure entailed by arterial contraction, and the constipation which is always produced by astringents, must be regarded as undesirable results.

Ergot is said by some writers to cause dilatation of the veins, and thus to reduce the arterial tension, but, whether this be so or not, the action of ergot is as uncertain and unsatisfactory as that of other styptics. The powerful effect of ergot in controlling bleeding from a contractile organ like the uterus cannot be expected in the case of hæmorrhage from the lung, which is unprovided with muscular tissue. Inasmuch, therefore, as tangible objections exist to the use of styptics, it seems preferable to attempt to lower the blood-pressure by rest, low diet, and saline purgatives, combined, if necessary, with opium. A mixture containing sulphate of magnesia 60 grains, with sulphate of soda 20 grains, may be given every four hours till looseness of the bowels is produced, the same remedy being continued for a few days in less frequent doses, so as to maintain a watery flow from the intestine.

If cough or restlessness be troublesome, morphine in small repeated doses should be administered by the mouth; or, better still, $\frac{1}{2}$ grain of the drug may be injected under the skin. Turpentine is sometimes useful, $\frac{1}{2}$ drachm of the oil being followed by a few doses of 20 minims at intervals of two or three hours.

Tartar emetic in doses of about $\frac{1}{2}$ grain is recommended by some physicians.

If styptics be preferred, the following drugs are those commonly used:—Ergot, in the form of the liquid extract, 1 to 3 drachms, followed by 20 minims every half-hour or hour for a few doses; or

ergotin, 1 to 2 grains hypodermically; gallic acid, 20 grains every hour or two; acetate of lead, 3 grains every three hours; sulphuric acid, 30 minims, in combination with alum, 20 grains, every three or four hours.

The constipation commonly produced by astringents must be obviated by the use of purgatives. Counter-irritation to the chest wall may be employed as an adjunct to other measures. The use of the ice-bag, so popular in Germany, does not find much favour in this country.

The artificial production of pneumothorax has been practised in persistent hæmoptysis with the view of causing collapse of the lung and pressure on the bleeding vessels.

The probable existence of pleuritic adhesions and of consolidation of the lung at the seat of hæmorrhage, the possibility of puncturing the wrong side, and the shock entailed by the operation are among the objections which seem fatal to the adoption of this heroic measure.

Great care is needed in the resumption of exercise, ordinary diet, and stimulants, owing to the tendency of hæmorrhage to return. The patient should be confined to bed, on a very sparing diet, as long as blood continues to be expectorated.

In cases of false hæmoptysis dependent upon oozing from the gums or upon naso-pharyngeal hæmorrhage, local astringent applications should be combined with the treatment of anæmia or other disorder of the general health.

PERCY KIDD.

HÆMORRHOIDS (Piles).—Local enlargement and varicosity of the hæmorrhoidal veins.

When formed by dilatation of the veins which underlie the mucous membrane within the external sphincter ani muscle, they are termed *internal piles*; when formed external to that muscle, and therefore covered with integument, they are called *external piles*.

Hæmorrhoids from which blood is discharged are often spoken of as *bleeding piles*; and those which do not bleed as *blind piles*; when existing in a painless condition they are described as *indolent*.

External Hæmorrhoids, when in an active state, appear as softish, rounded tumours of the integument at the verge of the anus, livid in hue, and tender to the touch. When the congestion is increased, as by the passage of a costive motion, the pile becomes more swollen, tense, and tender. This congestion may

subside, and the contained blood-clot—which is formed at an early stage of the process—may be gradually absorbed, so that the site of the pile becomes occupied by a flattened, more or less plicated, and almost insensitive, fold of hypertrophied integument. Or the congestion may run on into inflammation, with a corresponding increase in the size, redness, tension, and tenderness of the tumour; and this inflammatory condition may undergo remission, with subsequent recurrence from time to time, or may completely subside, with the result already indicated. Or, again, an inflamed pile may suppurate, the little abscess bursting with a discharge of mingled blood and pus, and eventually healing with obliteration of the enlarged vessel and consequent cure of the local mischief.

Bleeding is quite exceptional in the case of external piles.

Internal Hæmorrhoids often fail to attract the patient's attention until they have grown into tumours sufficiently long to protrude at the anus during defæcation. They then appear as one or more tumid swellings of the mucous membrane, which, if the piles be inactive and the sphincter relaxed, present as softish tumours with a granular surface. If congested, inflamed, or strangulated by the sphincter, they appear as protuberant, dark red, tense, smooth-surfaced tumours, painful, and bleeding readily. Large internal piles of old standing often induce more or less eversion of the anal margin, and in such cases it is important not to mistake the encircling ring of everted skin for external piles, as its excision is apt to be followed by troublesome contraction of the anus.

Large internal piles which have protruded beyond the sphincter muscle are liable to become constricted and *strangulated*; an extremely painful congestion and inflammation follows, which may result in the gangrene and sloughing off of the more external portion of the tumours thus affected.

Sometimes internal piles are more sessile in character, existing mainly as flattened nœvoid swellings of the mucous membrane, and rarely or never protruding beyond the anus.

Internal piles are very prone to bleed, especially when to their congestion is added the local irritation caused by the passage of bulky and constipated motions. The amount of blood lost at stool may vary from a few drops to as much as several ounces; it may occur

only at the time of defæcation—and in this respect may be quite irregular, or may exhibit a marked tendency to periodical recurrence or to periodical increase. Sometimes the hæmorrhage takes place within the bowel, quite independently of defæcation. The blood lost is often dark and venous in character. But the longer a pile exists in an active state, the more dilated do all the blood-vessels within it and its immediate neighbourhood become; and in such cases arterial hæmorrhage, even to the forcible spouting of bright red blood, is both common and severe.

Both internal and external hæmorrhoids may co-exist in the same individual.

Symptoms.—*External Piles* are accompanied by a sensation of tenderness, heat, and irritation at the anal margin. When congested or inflamed, the feeling of heat and pain becomes proportionately increased, and renders sitting uneasy or even intolerable. At the same time there is apt to be more or less of the malaise and general irritability of temper or despondency which is usually experienced in connection with a congested state of the portal system.

Internal Piles, during the earlier stage of their development, may be productive of no appreciable symptoms, or, at most, of some sense of fulness and uneasiness within the rectum, and occasional or persistent pain in the back.

The next stage is marked by the occasional loss of small quantities of blood during or after the passage of a constipated motion, and increased heat and irritation just within the orifice of the bowel. Then the piles begin to protrude during defæcation, but return within the sphincter again on completion of the act. Later, they always protrude at stool—and to a greater extent—and their return within the bowel needs to be assisted with the fingers; they also bleed more readily and to a larger amount.

Finally, as the mucous membrane becomes more hypertrophied and the sphincter muscle more relaxed, the anus tends to become everted, sore, and inflamed, and the piles constantly protrude whenever the patient assumes the erect, or even the sitting, posture: while abrasion and irritation of the everted tissues induce a constant muco-purulent and sanguinolent discharge which stains the patient's linen. Defæcation becomes exceedingly painful and there is often more or less irritation about the neck of the bladder, or of the uterine system.

All these symptoms are aggravated—

as, at first, they are only experienced—after any excess at table, or in alcohol, or by some similar imprudence which induces local congestion and spasmodic contraction of the sphincter.

If hæmorrhage occur to a marked extent, or be frequent or continuous, the patient's complexion becomes pallid or sallow, and he may exhibit all the symptoms of profound anæmia (*q.v.*).

Ætiology.—Some persons seem to exhibit a constitutional, and others possibly an hereditary predisposition to the development of piles. This is directly favoured by all conditions that impede the portal circulation and determine a flow of blood to the intra-pelvic organs—*e.g.*, sedentary habits, overfeeding and overdrinking, sexual excess, urinary disorders, flexions of the uterus, pregnancy; cardiac, respiratory, and hepatic disease; local chill, constipation, violent purging, and the abuse of aloetic aperients.

The malady is exceptional before puberty, but is rarely altogether escaped in later years, and is common in middle and advanced life. Men suffer more than women; but women who have borne children are, for obvious reasons, liable to the development of piles.

Treatment.—If the portal system be congested, it should be unloaded by a mild mercurial cathartic; and the action of the bowels must be so regulated that they are every day *sufficiently* relieved by the easy passage of a softish motion, but without any intestinal irritation or excessive purging. The confections of senna and of sulphur, the compound liquorice powder, or a dose of aperient mineral water taken every morning on rising, are suitable to this end.

The patient should take abundant exercise in the open air, and must use cane- or wood-seated chairs, avoiding all softly cushioned seats. Rich and highly seasoned dishes as well as alcohol must be abstained from; and the abdomen, legs and feet should be warmly clothed.

Eight or ten ounces of cold water injected into the rectum every morning is a very useful measure; and some astringent—such as ice, tannic acid, rhatany, hazeline, or alum may be added to the water, if advisable, in order to control venous bleeding; or an astringent suppository may be used. The orifice of the bowel should be cleansed with cold water after each defæcation, and any protruding piles should be at once pressed back within the sphincter by the fingers smeared with simple oil, or anointed with the unguentum gællæ cum

opio, or with an ointment containing cocaine and acetate of lead.

A few 2-drachm doses of the liquid extract of coca leaves will often check the venous bleeding and other symptoms of congested internal piles; and a mixture containing sodium or magnesium sulphate, sulphate of iron, glycerine and dilute sulphuric acid is useful in such cases.

In persons suffering from general plethora, lack of sufficient exercise, excess at table, or from any form of congestion of the liver or kidneys, it is unwise to check completely or too suddenly the venous hæmorrhoidal bleeding, which may serve as a useful safety-valve; and under these conditions a course of alkalies with a little colchicum and careful hygienic management are often all that is needed for gouty subjects. But arterial bleeding from piles is never beneficial to health; nor is it so amenable as the venous variety to merely medicinal treatment.

Whenever hæmorrhoids, be they internal, or external, are very large and troublesome, or the cause of excessive hæmorrhage, they must be treated by surgical operation. External piles may be simply snipped off with scissors and their bases touched with some styptic; or they may be ligated, or injected with carbolic acid liquefied by glycerin. Internal piles are treated by the application of the ligature, or of strong nitric acid, or by the cautery; or they may be crushed by an appropriate clamp.

C. E. SHELLY.

HÆMOSTATICS (Styptics) are remedies used to arrest hæmorrhage. They act either by promoting coagulation of the blood in the vessel, or by causing contraction of the bleeding vessel. To the latter group belong nitrate of silver, acetate of lead, and ergot, the latter or its active principle, sclerotinic acid, being especially useful when given hypodermically; cold and heat are also powerful agents belonging to this class. The other group includes all the substances which tend to promote precipitation of albumen, and so to hasten the coagulation of the blood. They have already been enumerated under the head of Constringents (*vide* ASTRINGENTS).

HAIR, DISEASES OF THE.—Certain affections of the hair are described elsewhere under the headings ALOPECIA and CANITIES. In this article only such diseases are included as are but little likely to be sought for under their proper titles.

Hirsuties (Hypertrichosis) denotes hypertrophy or superabundance of hair.

The affection assumes various forms: thus, normal hairs may increase in size and length, *e.g.*, on the eyebrows, nostrils, ears; or coarse pigmented hairs may grow upon regions normally provided with lanugo.

The development of hair is closely correlated with maturation and disease of the genitalia. In both sexes sexual precocity is accompanied by premature development of pubic and axillary hairs; at the menopause, or in consequence of menstrual disorders, women are often disfigured by growth of hair about the chin and lips, and a similar condition occasionally occurs during pregnancy (*H. gestationis*). The presence of long, coarse hairs on congenital or acquired moles is very frequent. More rarely a temporary hirsuties results from spinal disease or nerve injuries, or from local irritants employed therapeutically.

Certain tribes in Japan (*Aïnos*) are covered with coarse hair. Among Europeans, hirsuties is often hereditary, the teeth being also badly developed; by some, the condition is considered as illustrative of atavism, or reversion of type.

Treatment ought to be directed to the cause. Caustic pastes are sometimes used, but their employment is to be deprecated, as they are apt to produce excessive irritation, and the hair which subsequently appears is generally more abundant and more deeply pigmented than before. Destruction of superfluous hairs by electrolysis is a satisfactory operation in suitable cases—*e.g.*, where the hair is dark and strong, the growth localized and not progressive. A fine needle connected with the negative pole of a galvanic battery is introduced into the hair follicle; the circuit is then closed, slight frothing occurs, and an urticarial wheal forms, from the centre of which the hair, when quite loose, is detached with forceps. The little operation is rather painful. The minute scar which necessarily results ought to cause no perceptible disfigurement. A current strength of 4 to 5 milliampères employed for thirty seconds is sufficient to destroy each hair.

Trichiasis denotes an abnormality in direction of the growth of the hair, most commonly observed in the eyebrows and eyelashes. In the latter situation, the hairs often turn inwards, and cause conjunctivitis. They are best extirpated by electrolysis.

Fragilitas crinium implies brittleness of the hair-shaft, and is a symptom of many diseases, especially those which induce morbid dryness of the skin—*e.g.*, diabetes, seborrhoea, tinea tonsurans. On traction, the hair-shafts are easily fractured. Occasionally, the distal end of the shaft splits, or the hair splits within the follicle and appears on the surface like a minute wisp.

Treatment consists in the use of pomades or simple oils.

Trichorexis nodosa is a disease characterized by brittleness of the hair-shaft and by the development upon it of fusiform, bulbous, nodular swellings of a whitish colour, easily mistaken for "nits." It affects the beard and moustache more frequently than the hairs of the scalp, and causes considerable disfigurement.

The nodal expansions are distributed irregularly along the shaft, the internodal portions of which are quite healthy; at the nodes, the medullary substance is absent, and the cortex is distended and stretched by an accumulation of air. Fracture takes place at the nodes, and the brush-like ends may interlock, maintaining the continuity of the hair, but often at an acute angle. Nothing is known of its ætiology, and even removal of the beard is seldom of avail, the succeeding hair having the same peculiarity.

Another rare variety has been described in which the nodes occur at regular intervals, giving the hairs a moniliform appearance; the internodal portions are much atrophied, and the medulla often absent, and it is here that fracture occurs.

Piedra is a parasitic disease somewhat similar to trichorexis. It is common in Columbia, and affects the hair of the scalp in women. Small, hard nodules surround, or are attached to one side of, the hair-shafts, which on microscopic examination prove to be masses of spores budding forth from one cell. Constant washing cures the condition.

Plica polonica is a matted, entangled condition of the hair, the result of personal uncleanness and the desiccation of accumulated purulent discharges accompanying pediculosis and eczema capitis. It was long considered a mysterious disease of nervous origin.

J. J. PRINGLE.

HALLUCINATION. — Hallucinations are sensory impressions which occur without the action of external stimuli, and must be carefully distinguished

from illusions, which are false perceptions of actual objects. Any of the special senses may be affected, including disorders of the sense of touch, tactile hallucinations, which are comparable to the paræsthesia of such nervous diseases as locomotor ataxy; and visceral hallucinations, which closely resemble the visceral paræsthesiæ of various spinal diseases; also organic sensations, such as nausea or faintness.

Hallucinations of hearing are the most common, and occur chiefly in delusional insanity and melancholia, but also in acute mania, more especially in the alcoholic variety of that disease. Hallucinations of sight are chiefly observed in mania and delirium, and are generally acute and temporary symptoms, whereas those of hearing may last for many years. Hallucinations of these two senses may be unilateral or bilateral, and may be simple, as visions of lines or spots, or sounds, as of buzzing, or complex, appearing as heavenly scenes or the sound of human voices. Hallucinations of taste and smell are generally associated; they are of much less common occurrence, and are of serious import.

GEORGE REVINGTON.

HANGING, DEATH BY.—In carrying out the extreme penalty of the law, owing to the adoption of the "long drop," death is now generally due to pressure upon the medulla oblongata or spinal cord, from fracture or dislocation of one or more of the cervical vertebrae; but in the other forms of hanging it usually results from asphyxia.

The proof that a person has met his death by hanging will depend upon the position of the body when found, the presence of certain external marks on the neck, and of the signs of asphyxia in the internal organs, and on the absence of any other cause of death. The external signs about the neck will depend upon the length of time the body has been allowed to hang after death, and the nature of the suspending cord. The mark on the neck is generally an oblique, hard, dry, yellowish, horny furrow, sometimes marked with superficial ecchymoses. A small ligature will, of course, produce a thin and deep line; when there are two marks, these usually cross, instead of being parallel. Similar appearances result if the body be suspended immediately after death; to prove that this had been done would be almost tantamount to proving that a murder had been committed.

The face is usually turgid, with blood-stained froth about the mouth and nostrils; the tongue is swollen and semi-protruding. In men, the penis is often semi-erect, an escape of prostatic fluid having taken place; in women, the genital organs may be turgid or blood-stained. Internally, the right side of the heart and the lungs will be found engorged with venous blood; the left side may be empty; there may also be fracture or dislocation of the cartilages of the larynx, or fracture of the hyoid bone; sometimes the middle and inner coats of the carotid artery are found to have been divided.

Hanging is generally suicidal; it is by no means necessary that the body should be completely suspended in the air in order that a fatal termination may ensue.

It is rare that an opportunity for *treatment* presents itself; when it does, the body should be immediately cut down, and the rope removed from the neck. A free supply of air and artificial respiration would afford the best prospect of restoring suspended animation; bleeding is sometimes useful.

HAY FEVER (Hay Asthma).—A catarrhal affection of the mucous membrane of the eyes, nose, and air passages, frequently combined with asthmatic paroxysms, and due to the action of certain irritants on an abnormally sensitive mucous surface.

Under this head are included, not only cases of true hay fever, due to the irritation of the pollen of grasses, but also cases of paroxysmal sneezing and vasomotor coryza, caused by the action of various irritants on the nasal mucous membrane.

Symptoms.—The attack may commence with irritation of the conjunctivæ, lachrymation, and an increased secretion from the Meibomian glands; some amount of chemosis is frequently present. There is a feeling of fulness and oppression in the head, pain across the frontal sinuses, and intolerance of light. After an interval of time, varying from a few hours to some days, the nasal mucous membrane becomes affected; or it may be primarily attacked, the affection of the eyes being secondary; in any case, the patient sooner or later complains of intense irritation and stuffiness in the nose, and the mucous membrane may swell to such an extent as to render breathing through the nose very difficult, or even impossible. There is also a profuse discharge from the nose (at first watery, afterwards

becoming muco-purulent), with incessant sneezing. The catarrhal condition may also extend up the Eustachian tubes, giving rise to deafness. In some cases the disease extends down the throat, causing a feeling of dryness and itching in the fauces; and if the bronchial mucous membrane be attacked, there will be cough and a sense of constriction across the chest. Well-marked asthma may accompany an attack such as above described, or it may constitute its chief feature, the symptoms of coryza being less marked.

As regards general symptoms, there may be a slight amount of pyrexia, but it is frequently altogether absent; the pulse is usually somewhat accelerated. The attacks have a depressing influence on the patient generally, and there may be evidences of gastric disturbance. Urticaria is sometimes associated with hay fever.

Diagnosis.—The catarrhal symptoms which mark the onset of the attack, and the occurrence of violent sneezing after exposure to a source of irritation, in typical cases the pollen of various grasses, usually suffice to render the diagnosis easy. The only cases which present any difficulty are those in which symptoms of asthma appear without a previous catarrhal stage; but these may usually be distinguished from ordinary asthma by the fact that the attack occurs by day, and that it can be traced to the inhalation of some irritant or odour.

Prognosis.—The great attention which has been paid to hay fever of recent years has resulted in a much more successful mode of treatment, so that in the majority of cases a cure may reasonably be expected; and even where this cannot be attained, great relief can be afforded.

Pathology.—In discussing the pathology of hay fever it will be necessary to include the subject of reflex nasal neuroses, as it is impossible to separate the one from the other. The writer is satisfied that, although Hack erred in attributing to diseased conditions of the nasal mucous membrane too great a rôle in the causation of various nervous affections, their influence in this respect is considerable. In addition to hay fever, asthma and paroxysmal sneezing, cough, migraine, supra-orbital neuralgia, redness and swelling of the nose, and giddiness have been found to owe their origin in some cases to abnormal conditions of the nose, and it has been shown that preternatural irritability of the Schneiderian

membrane, from any cause, renders it liable to respond to influences which are entirely innocuous to a healthy tissue. This explains the fact that, although thousands are exposed to sources of irritation, such as the pollen of certain grasses, only an exceedingly small number suffer any inconvenience therefrom.

The changes met with in the nose in cases of hay fever are usually of a hypertrophic character, and constitute the condition known as "hypertrophic rhinitis." The whole nasal cavity may be affected, or there may be only a puffy swelling of the inferior or middle turbinated bodies, or a patch of erosion on the mucous membrane. Polypi, and a deflection of the septum nasi, are present in some cases. In a case of prolonged duration, under the care of the writer, all symptoms ceased as soon as a perforation in the septum had taken place, thus apparently proving that the irritable zone from which the reflex stimulus started was situated on the septum. On touching the interior of the nose with a probe, parts of the mucous membrane will often be found to be hyperæsthetic, and it may be possible to start an attack of sneezing in this way. Whatever the local changes may be, a paroxysm of hay fever is invariably accompanied by swelling and engorgement of the erectile tissue, which forms so important an element of the inferior turbinated body, but which is also present in other parts of the nasal mucous membrane. This is followed by an increased secretion, at first purely serous in character, but which later may become muco-purulent.

Ætiology.—In every case of hay fever, at least three factors are concerned in the production of an attack—(1) a general nervous constitution of the individual; (2) a local irritability of the conjunctival or nasal mucous membrane; and (3) some direct exciting cause. As regards the first, it is to be noted that the greatest sufferers from hay fever are the English-speaking peoples, but it is also met with in other races, though much more rarely. An instance of it occurring in a negro has been recorded. As a rule, the victims are persons belonging to the educated classes, whereas labourers almost entirely escape. Inhabitants of towns are more prone to be attacked than country folk. Men are much more subject to the disease than women, and heredity exercises a powerful influence. The second factor has already been considered when speaking of the pathology

of the disease. The remaining factor is the direct exciting cause. Careful and prolonged investigation has shown that, in this country at all events, the pollen of certain grasses is the most powerful exciting cause of hay fever, but it is equally certain that other sources of irritation, such as dust, or even the perfume from some plants, or the odour of certain animals, are capable of starting an attack in those predisposed to it. Again, a bright light, heat, or touching the irritable zone may start an attack.

True hay fever usually begins at the end of May or the commencement of June, and lasts about five or six weeks, or even longer in severe cases.

Treatment.—Bearing in mind the three factors concerned in the production of the affection, it will be desirable, in the first place, to improve the general health of the individual as far as possible. The severity of many cases is aggravated by the injudicious use of stimulants. Doubtless the depression produced by the disease would seem to suggest the administration of alcohol in some form, but when its action in dilating the arterioles is considered, it will be seen that locally its effect is far from beneficial, to say nothing of the more remote evils that may result from its use. Morell Mackenzie speaks highly of 1 grain of valerianate of zinc with 2 grains of the compound assafoetida pill, given two or three times a day. Tincture of opium in 5 to 10 minim doses, either alone or in combination with the same quantity of the tincture of belladonna, has been highly praised. One medical man reports that $\frac{1}{10}$ of a grain of morphine with $\frac{1}{20}$ of a grain of atropine, administered subcutaneously three times a day, robbed the hay season of its misery so far as he was concerned, but the objections to recommending injections of morphine in chronic illness are so weighty that the drug should only be employed as a last resource. Another medical man speaks favourably of his personal experience of succus belladonnæ, $\frac{1}{2}$ drachm being added to 3 ounces of water, and a teaspoonful taken every hour until the symptoms are relieved; the same solution may be used as a lotion for the eyes. Bromide of potassium (10–20 grs.) with 3 minims of liquor arsenicalis is useful for allaying the nervous erethism met with in hay fever, while at the same time the arsenic has a tonic effect. Antipyrin in 10 to 30 grain doses twice a day has an excellent effect—it seems to have an anæ-

sthetic action on the sensory and secretory nerves of the nasal fossæ.

The second point to be considered is the removal of the patient from the exciting cause of the paroxysm. Many persons who suffer severely in the country are almost free from attacks at the seaside. A sea voyage, if time can be spared for it, generally proves beneficial. But if the individual cannot escape from the country, he should be instructed to wear out-of-doors “goggles” with pale-blue glasses, and, if he will submit to it, a blue silk veil of double thickness over the face. He should take life as quietly as possible, and should especially avoid exertion in the sun. On the least suspicion of the complaint commencing he should bathe the conjunctivæ with a solution of corrosive sublimate 1 in 3000, and the same solution may be cautiously sprayed up the nostrils. Plugging the nostrils with tampons of cotton-wool soaked in glycerin is very useful in some cases. Lastly, the greatest care should be taken to examine the nasal passages with the view to discover the presence of any departure from the normal condition. If a puffy swelling of the turbinated bodies exist, or the mucous membrane be hypertrophied, the use of the galvano-cautery can be highly recommended. The surface is first rendered anæsthetic by dabbing it with a 20 per cent. solution of cocaine. After an interval of five minutes the cocaine may, if necessary, be applied a second time. The galvano-caustic blade should then be drawn along the mucous membrane so as to score it freely, or the fine point may be passed into the tissue in several places. Whichever plan be adopted, as healing occurs contraction takes place, and the undue sensitiveness of the surface is thereby destroyed. More prominent hypertrophied tissue or polypi may be removed by the galvano-caustic loop. Similar procedures will be found of great service in cases of paroxysmal sneezing and other neuroses starting from the nasal mucous membrane. As regards the use of cocaine locally, the expectations which were formed of its efficacy in hay fever when the drug was first introduced have not been realized. Though the immediate effect of the application of a weak solution of cocaine to the nasal mucous membrane is to produce an alleviation of the most distressing symptoms of the disease, the effect soon passes off and the application has to be renewed. As a result of the dilatation

of the blood-vessels which is the secondary effect of cocaine, the mucous membrane increases in thickness, so that eventually cocaine aggravates the evil it was meant to cure. Moreover, the seductive effect of the drug should not be forgotten, nor the risk of starting the cocaine habit ignored. A 10 or 20 per cent. solution of menthol dissolved in almond or olive oil and applied to the nasal mucous membrane has yielded good results, and has none of the drawbacks of cocaine. Sir Andrew Clark has proposed a plan of treatment by which the irritability of the nasal mucous membrane is exhausted. An ounce of glycerin of carbolic acid, 1 drachm of hydrochlorate of quinine, and a two-thousandth part of perchloride of mercury are made into a solution by the aid of heat, and the interior of the nostrils is freely swabbed out with the mixture. He claims a fair measure of success for this plan—*i.e.*, about half of those whose cases he was able to follow were cured for the season, and four persons were cured "for good." If a more radical treatment be out of question, or be objected to by the patient, anointing the interior of the nose with an ointment consisting of 1 ounce of vaselin and a drachm of oil of eucalyptus, with or without a drachm of the solution of atropine B.P., as suggested by Lennox Browne, will be found useful. Among minor remedies which have been found of use in alleviating some of the symptoms of hay fever may be mentioned carbolized smelling salts, the formula for which is pulv. carbonis ligni; ammon. carb., āā ʒij; tr. benzoini co., ʒj; acidi carbolic, ol. lavandulæ, āā ℥x; liq. ammonii fort., q.s.; misce bene; also the inhalation of benzoin, a drachm of the tincture in a pint of hot water, and the use of a spray of a 25 per cent. solution of rectified spirit.

F. DE HAVILLAND HALL.

HEADACHE (Cephalalgia) is a symptom occurring in the course of a great variety of diseases. It may be due to organic cerebral disease, congestion and anæmia of the brain, functional nervous disorders, toxæmic conditions and derangements of the stomach and liver. The character of the pain varies considerably; it may be superficial or deep, constant or paroxysmal, general or local, dull and heavy or throbbing and stabbing.

Headache is frequently the first symptom and occurs in nearly every case

of meningitis, and of tumour or abscess of the brain. The pain is rarely paroxysmal, but usually constant and liable to exacerbations, which may be of the most excruciating description. It is frequently circumscribed, but is of little or no localizing value unless the lesion be superficial. In some cases of syphilis of the meninges or cortex, and of superficial abscess, pain is referred to a spot which is extremely sensitive to pressure. On the other hand, the seat of the pain may be far distant from the lesion—so far, indeed, that frontal headache has been known to occur in disease of the occipital lobes. On the whole, pain referred to the occiput is of far more diagnostic importance than if it be frontal.

Headache also occurs in many functional nervous disorders. One of the commonest of these is migraine, which will be found discussed under that head. It need only be said here that there are many imperfectly developed forms of that affection, and that headache unaccompanied with vomiting or any sensory disturbance is one. Among hysterical women and highly strung, sensitive, emotional people, and especially girls, who are perhaps also precocious, headache is a common symptom, and may resist every form of treatment. In these cases there is often a neuralgic element, which, if not the source of the headache, gives it a distinct colouring, and justifies its name of neuralgic headache. The pain may be general or local, is not paroxysmal, and may persist for days. Hysterical women sometimes experience a vertical headache, which is usually described as boring, and like that which might result from the driving of a nail into the top of the head. It thus receives the name of "clavus hystericus."

Headache is common in cases of nerve exhaustion proceeding from almost any cause, and particularly from prolonged mental effort or worry. It may be a result of anæmia, and is then commonly frontal, or may be due to congestive states of the brain resulting from heart disease, asthma, and other forms of dyspnœa. In these latter cases it is throbbing in character, and, as in nearly every other variety of headache, is increased by stooping, coughing, and any other condition which tends to increase the congestion.

Frontal headache is frequently the result of errors of refraction, especially hypermetropia and astigmatism. In

many of these cases there is occipital pain of a neuralgic nature, and sometimes a painful area on the scalp, the hair of which feels as if it had been "slept on the wrong way."

Toxæmic headache may result from chronic alcoholism, uræmia, lithæmia, fevers, secondary syphilis, or diabetes. In most of these cases it is frontal and deep-seated, and is sometimes very severe; in uræmia, indeed, it may be so overwhelming as to raise the suspicion of cerebral tumour. That of secondary syphilis is of the neuralgic type, limited to the temples, and recurring with great regularity every evening. In lithæmic subjects indiscretions of diet or constipation may induce headache, which, coming on in the morning, may last a short time or persist for days. Badly ventilated or overcrowded rooms, in which respired air is necessarily breathed, readily produce, in many people, a heaviness or actual pain in the head. The same thing is often experienced before a thunderstorm, when the air is so still that the products of respiration are not carried away. Headaches resulting from stomachic and hepatic derangements are possibly also toxæmic in origin. They are usually occipital or vertical, but may also be frontal or generally distributed.

Treatment.—This must be mainly directed towards the condition which is the cause of the headache. Little can be done to alleviate the agonizing pain of organic cerebral disease other than syphilitic. If narcotics be prescribed, it should be remembered that sudden death is by no means rare in these cases, and may possibly be ascribed to the drug if no warning have previously been given to the patient's friends. Toxæmic headache is often relieved by diuretics and mild aperients. Anæmic states must be treated with iron, and in these and some other cases arsenic is also of use. In all cases of doubtful origin the eyes should be examined, and any error of refraction remedied by the use of spectacles. The instillation of atropine into the eyes for a week or two is of great service when the headache depends upon spasm of the ciliary muscle. Paroxysmal and neuralgic headaches should be treated on the same principles as neuralgia. In these the administration of quinine, arsenic, gelsemium, butyl-chloral, cannabis indica, and antipyrin meets with success in different cases, but, in addition, the general surroundings and habits of the patient must be carefully considered. Local applications are

of comparatively slight value; but a mustard plaster applied to the nape of the neck sometimes greatly relieves an occipital headache, and menthol and stimulating liniments, such as chloroform, belladonna, or aconite, are occasionally distinctly beneficial.

WILLIAM GAY.

HEART, DISEASES OF THE MUSCULAR WALLS.—The diseases of the cardiac walls, viewed from the standpoint of pathological anatomy, are many and various, including degenerative, inflammatory and suppurative affections, fatty infiltration, simple atrophy and morbid growths of different kinds. In addition to these well-recognized conditions, it is probable that the myocardium and its nervous apparatus are liable to fine molecular changes, which cannot as yet be precisely defined, but which may constitute the starting-point of certain forms of dilatation and failure of the heart and of some of the so-called functional disorders of the organ.

The degenerative group comprises granular, fatty, fibrous, amyloid, pigmentary, vitreous and calcareous transformations.

Myocarditis, or acute inflammation, evinced by a cellular exudation, is practically always consecutive to pericarditis or endocarditis, but is said to have been found without concomitant disease of the pericardium or valves in isolated instances.

Abscess of the heart's wall is usually multiple, and is a symptom of pyæmia or allied conditions, such as ulcerative endocarditis, in which minute infective emboli become impacted in the branches of the coronary arteries.

The morbid growths to which the heart is liable are carcinoma, sarcoma, lympho-sarcoma, lipoma, myoma, fibroma, myxoma, tubercle, syphilitic gummata, hydatid cysts and cysticercus. Malignant growths are almost invariably secondary to similar disease within the thorax or in other parts of the body, though instances of primary sarcoma and lympho-sarcoma have been recorded. The commonest forms of morbid growths are secondary carcinoma and tubercle, the latter being associated, as a rule, with pericardial tuberculosis. All other growths are extremely rare.

Simple atrophy of the heart may occur in many different diseases, but is devoid of any special clinical significance.

Morbid conditions of the cardiac walls are only of clinical importance in so far

as they lead to interference with the functions of the heart. Lesions of the myocardium, of whatever kind, when they are of sufficient degree and extent, have as their necessary consequence impairment of the heart's contractile power.

In the present state of our knowledge it is in most cases impossible during life to differentiate with any degree of accuracy the various morbid changes to which the myocardium is liable. Our recognition of these affections is based partly upon the effects which they produce on the heart itself and on the peripheral circulation, and partly on a consideration of the general condition and history of the individual patient. By this means we are at times enabled to diagnose the disease; nevertheless, though we may suspect the presence of a certain lesion, and may happen to be right occasionally, we can seldom arrive at an accurate anatomical diagnosis.

In this article the general pathology of disease of the cardiac walls will be first considered, those affections which seem to require special notice, such as **FATTY and FIBROID DISEASE, DILATATION and HYPERTROPHY FROM OVERSTRAIN**, being treated separately.

GENERAL CONSIDERATION OF MYOCARDIAL DISEASE.—Impairment of the heart's contractile power, as shown by cardiac weakness or insufficiency, is the fundamental point from which our diagnosis must start in all myocardial affections.

Dilatation.—As a necessary result of muscular weakness, the walls of the heart yield to the intra-cardiac blood-pressure, and some or all of the chambers undergo dilatation according to circumstances. Such dilatation must be distinguished from the temporary distension which is the consequence of physiological increase of the heart's work. A rise of tension in the systemic arteries, induced by muscular exertion or other causes, leads to heightened pressure in the left ventricle in the first instance, but this condition soon reacts backwards on the left auricle, the pulmonary circulation and the right heart, the result being a general increase of intra-cardiac pressure. The moderate distension of the heart induced by physiological causes is unaccompanied by any failure of the circulation, for the heart is possessed of a remarkable fund of reserve force, which enables it to meet increased demands on its functional activity within very wide limits. When the cause of the increased intra-cardiac pressure is removed—for example, when

violent muscular exercise is discontinued—the heart regains its normal size without any resulting deterioration of its muscular fibres.

Pathological dilatation differs from physiological distension in that it entails some degree of disturbance of the circulation. In this instance the enlarged condition of the cardiac chambers is more or less persistent, the cause being abiding, as in the case of extensive myocardial degeneration or valvular disease; or, if temporary, acting with great intensity—for example, the dilatation due to overstrain of the heart.

The development of pathological dilatation may be associated with gross changes in the muscular tissue of the heart, such as fatty degeneration; but more often no anatomical alteration can be detected with our present appliances. It is probable, notwithstanding, that some subtle molecular changes are intimately connected with the occurrence of dilatation. No sharp line of distinction can, however, be drawn between slight degrees of pathological dilatation and physiological distension. Enlargement of the heart's cavities probably represents an exaggeration of the normal state in each case.

Experiments on the healthy living heart (Roy and Adami) have shown that, although the greater part of the ventricular cavity is obliterated during systole, a certain amount of blood always remains in the upper part of the chamber, between the valves and the papillary muscles. When the resistance to the discharge of blood from the left ventricle into the arteries is increased, the amount of this residual blood becomes larger, and the ventricle now contains more blood during diastole as well as systole. When, as commonly happens at first, the quantity of blood poured into the heart from the veins in a given time remains unchanged, the left ventricle at the end of diastole contains the normal quantity received from the auricle and lungs, plus the increased residual blood that remained in the ventricle at the close of the previous systole. Enlargement of the ventricular cavity is, therefore, a necessary consequence.

This diastolic distension may be temporary or persistent. If the reserve force of the cardiac muscle be not exceeded, the quantity of blood discharged from the ventricle at each systole suffers no important diminution, and no circulatory derangement occurs. When, on the other hand, the mechanical work required of

the heart reaches a certain point, which differs widely in individual cases, the limits of the heart's power of accommodation are exceeded. The ventricle can no longer sufficiently empty itself into the arterial system owing to exhaustion of its muscular fibres, and the amount of blood discharged at each systole falls below the normal. The cardiac walls yield to the internal pressure, and blood gradually accumulates in the distended ventricle, with consecutive dilatation of the left auricle and right heart.

When the engorgement becomes excessive, the muscular fibres of the auriculo-ventricular rings become stretched, the less yielding mitral and tricuspid curtains no longer completely close the dilated orifices, and regurgitation ensues. The immediate effect of dilatation of the left ventricle is seen in incomplete filling of the arteries, owing to the feeble contraction of the muscular walls. This diminution of the driving power of the ventricle is speedily followed by backward congestion, reacting first on the lungs, and subsequently on the right heart and veins of the systemic and portal circulation.

Dilatation of the heart may be due to increased work, or to changes in the muscular walls tending to impair their contractility. The work of the heart may be raised by an increase in the volume of blood which it has to discharge in a given time, or by increased peripheral resistance in the arteries or capillaries.

The left ventricle has been taken as a type of the heart generally; but what has been said of this chamber applies with equal force to the heart as a whole.

In the preceding remarks enlargement of the heart's cavities has been alone considered, but it is in all probability true that pathological dilatation is always accompanied by a varying amount of hypertrophy of the muscular walls.

Hypertrophy is generally divided into three classes—(1) simple hypertrophy, where the walls are thicker than usual, the size of the cavities remaining unchanged; (2) concentric hypertrophy, where the size of the heart remains the same, but its walls are increased in thickness and encroach upon the capacity of its chambers; (3) excentric hypertrophy, where the heart is both dilated and hypertrophied.

Simple hypertrophy is perhaps found in some cases of renal and other diseases, but excentric hypertrophy is the condition almost always met with. The ex-

istence of concentric hypertrophy is very doubtful. Many fallacies arise on the post-mortem table, not only in estimating the relative degree of hypertrophy and dilatation, but even in determining the very existence of these conditions. The varying amount of "rigor mortis" or relaxation met with in different cases is a fruitful source of error, and an accurate decision is at times impossible. The weight of the heart is probably the best test of hypertrophy that we possess. Increased thickness of the heart's wall is mainly, if not entirely, the result of a numerical hypertrophy of the muscular fibres, though a few authors have contended for the enlargement of the primitive fibrils.

Some writers divide hypertrophy into two further categories, *true* and *false*. In true hypertrophy the muscular tissue itself is increased, whereas in the false variety the thickening is due to some extent to an adventitious fibrous growth. In speaking of hypertrophy we shall refer to true hypertrophy only.

The origin of hypertrophy is to be sought in every case in some increase in the work required of the heart. A rise of arterial pressure representing augmented resistance to the ventricular discharge must therefore tend to produce hypertrophy. Taking the left ventricle as a type, we have seen that increased peripheral resistance in the arteries involves enlargement of this chamber. As the ventricle must now contain a larger amount of blood, more powerful contractions are required to propel its contents; in other words, the work of the ventricle is increased. Thus it appears that dilatation is indirectly a cause of hypertrophy. Valvular defects also throw extra work on the heart, and are prolific sources of hypertrophy and dilatation.

When a hindrance to the circulation occurs in the systemic arteries and capillaries, or in the aorta itself, the walls of the left ventricle and auricle undergo an increase in thickness in the first instance, though eventually a certain degree of hypertrophy is manifested by the right heart also.

The main causes of hypertrophy of the left heart are—(1) certain valvular diseases; (2) diseases of the aorta and its branches, involving loss of elasticity of their coats, which may or may not be associated with narrowing or dilatation of their lumen; (3) diseases of the kidney, especially cirrhosis; (4) stenosis or coarctation of the aorta at the point of entry of the ductus arteriosus; (5) general

contraction of the arterioles from prolonged muscular exercise or from other causes.

The causes of hypertrophy of the right side of the heart are to be found in conditions that occasion obstruction to the pulmonary circulation, or that interfere with the passage of blood through the right heart, viz., certain valvular affections, and chronic diseases of the lungs, *e.g.*, emphysema, cirrhosis, collapse and phthisis.

The following doubtful causes of hypertrophy of the heart may be mentioned:—Plethora or an increase in the volume of blood, pregnancy, over-action of the heart from nervous causes, and adherent pericardium. The last condition is considered under the head of PERICARDITIS. For the development of hypertrophy certain conditions are required in addition to increased work. In the first place, an adequate circulation of healthy blood through the coronary arteries is of vital importance for the nutrition of the myocardium. In wasting diseases, such as carcinoma and phthisis, the mechanical conditions necessary for the development of hypertrophy may be present without any corresponding increase in thickness of the cardiac walls, owing to the impoverished state of the blood. It is obvious that hypertrophy once established will itself tend to promote a more rapid and copious flow of blood through the coronary arteries. Secondly, distension of the heart's cavities must not be too sudden or excessive, the effect of this being seen in a paralytic dilatation of the heart, as is the case in asphyxia.

Hypertrophy, being the result of increased demands on the heart's functional activity, is essentially a conservative process. The strengthening of its muscular power enables the heart to overcome in a greater or less measure the obstacles which have called forth the hypertrophy. Another important and beneficial result of hypertrophy of the cardiac walls consists in an augmented power of resistance to the internal pressure of the blood, which is manifested by a diminution or disappearance of the signs of dilatation. Hypertrophy is therefore fitly described as *compensatory*. The existence of compensation is revealed to us by restoration of the circulation, by certain alterations in the heart itself, and by removal of the consequences of its previous disturbance, such as arterial anæmia, venous stasis, and their effects.

Hypertrophy of the heart may be sufficient or insufficient, but is never excessive—one of the many proofs we have of the complex powers of adjustment possessed by that organ.

The functional effects of dilatation and hypertrophy are combined with certain changes in the heart itself. Dilatation frequently causes thrombosis in the different chambers owing to the slowing of the circulation. Cardiac thrombi sometimes attain to a considerable size, and may give rise to mechanical interference with the blood-stream. More frequently, by detachment of fragments, they afford materials for the production of embolism in other organs. Thrombosis of the right heart is a common source of pulmonary embolism. Fibrinous emboli derived from the left side of the heart may become impacted in the arteries of distant organs, such as the brain, kidneys, spleen, or even of the heart itself. The subject of embolism of the various organs is treated under that heading; the consequences of coronary embolism are described in the article on FIBROID DISEASE OF THE HEART (*q.v.*).

The high pressure which prevails in dilated and hypertrophied hearts leads, in course of time, to more or less fibrous thickening of the valves, papillary muscles, chordæ tendineæ and endocardium, both sides of the heart or only one side being involved according to circumstances. Hypertrophied and dilated hearts are prone to degenerative changes in their muscular walls; parts like the left ventricle, with its papillary muscles, which are most liable to high pressure and whose functional activity is greatest, showing a special tendency to undergo these changes.

Owing to its increased size and weight, the heart is apt to fall downwards and take up a more transverse position, depressing the diaphragm, and interfering with the free action of this important muscle. Respiration is further impeded by the encroachment of the enlarged heart on the intra-thoracic space. Emphysema of the anterior margin of the lungs is not uncommon in such cases, and is partly the result of concomitant bronchitis, but is also to some extent to be regarded as compensatory.

The influence of hypertrophy is also shown by certain alterations in the vessels, especially in the arteries. Thus hypertrophy of the left ventricle of long standing may cause endarteritis of the aorta and its branches in consequence of the strain to which they are exposed

by the powerful stroke of the ventricle. A similar condition may also be observed in the pulmonary artery when it is subjected to very high pressure from hypertrophy of the right ventricle.

Symptoms and Course.—From the preceding remarks it will be evident that the symptoms of myocardial lesions must depend on derangement of the heart and peripheral circulation. The subjects of such disease may present some or all of the symptoms common to all severe cardiac disorders. Dyspnœa, palpitation, a sense of constriction, pressure, uneasiness or actual pain in the region of the heart are often complained of. At times such symptoms as headache, drowsiness, apathy, giddiness, flatulence, epigastric pain or weight after food, nausea, vomiting, constipation, diarrhœa and hæmorrhoids, depending on venous stasis of the cerebral or gastro-intestinal vessels, so engross the attention of the patient that he omits all mention of the more characteristic cardiac symptoms. Varying degrees of cyanosis and dropsy are seen in different cases. While it may be said that no single symptom is pathognomonic of disease of the heart, the association of dyspnœa and palpitation with signs of venous congestion and dropsy is very significant of the existence of cardiac failure, though no information is thereby afforded as to whether the disturbance of the circulation is primarily cardiac.

Dyspnœa.—Of all the symptoms just enumerated dyspnœa furnishes the most constant and important information as to the functional activity of the heart. Dyspnœa may be defined as increased action of the muscles of respiration, whether as regards frequency or degree of contraction. This symptom is described in somewhat different terms by patients. Some complain of a difficulty or tightness of breathing—that is to say, the act of respiration is laborious. Others say that they have no difficulty in the mechanical performance of respiration, but their utmost efforts fail to remove the distressing sensation of shortness or want of breath—the “air-hunger” of the Germans.

Dyspnœa may be either inspiratory or expiratory, according as it is mainly manifested by the muscles of inspiration or expiration; or it may be general—that is to say, both inspiratory and expiratory. Inspiratory dyspnœa is characteristic of obstruction of the larynx and trachea. The dyspnœa of bronchial asthma is typically expiratory. Cardiac

dyspnœa, on the other hand, is both inspiratory and expiratory.

The *pathology* of cardiac dyspnœa is less simple than it seems at first sight. An excess of carbonic acid or a deficiency of oxygen in the blood, the two being for the most part combined, provokes increased action of the respiratory muscles. This effect is partly the result of stimulation of the respiratory centre in the medulla oblongata by the altered blood, but another influence is probably also concerned. The asphyxial state of the blood at the same time excites the vaso-motor centre, the effect of which is seen in contraction of the small arteries throughout the body and in a rise of blood-pressure. Recent experiments have shown (v. Basch) that increased tension in the systemic arteries, in whatever manner it may be produced, is invariably followed by a rise of pressure not only in the left side of the heart, but also in the pulmonary circulation and right heart. The same author has shown that when the tension in the pulmonary vessels is raised the lungs swell up and become more rigid. In virtue of this change increased efforts on the part of the muscles of respiration are required to produce the requisite degree of expansion. This rigidity of the lungs is due to a sort of erection depending on distension of the capillaries, which unfolds the alveolar walls, and thereby enlarges the lumen of the air sacs. Basch believes that this condition, if long continued, may lead to vesicular emphysema.

Dyspnœa, or the increased activity of the respiratory muscles, is thus explained to be the result of vascular turgescence on the part of the lung. Cardiac dyspnœa had long been attributed by other authors to pulmonary congestion, but this was supposed to operate by impeding the entry of air into the alveoli, the consequent accumulation of carbonic acid in the blood being followed by stimulation of the respiratory centre. Basch, however, was the first to point out the mechanical effect upon the lung produced by engorgement of its vessels. This view is applicable not only to cases of high arterial tension, but also to the opposite condition, in which the blood-pressure is lowered as the result of weakness or insufficiency of the left ventricle, for in the latter event the dilatation of the ventricle allows the blood to collect in its cavity, and must have the effect of inducing a backward congestion of the pulmonary vessels and right heart. Pulmonary engorgement is

a result common to widely different affections of the heart, and may be regarded as the main element in the production of cardiac dyspnoea in virtue of a twofold action—(1) direct, on the lung, producing alveolar erection and rigidity; (2) indirect, on the respiratory centre, through the influence of asphyxial blood.

The dyspnoea of cardiac patients may be due to other causes also. Any diminution of the aërating surface of the lung by its interference with the diffusion of gases in the blood of the pulmonary capillaries will co-operate in producing dyspnoea, owing to the stimulating effect of the altered blood on the respiratory centre. Thus, pleural effusions compressing the lung, consolidation, collapse or œdema of the lung, bronchitis and emphysema are all in themselves efficient causes of dyspnoea, and may complicate any case of heart disease, but in such conditions the dyspnoea is no longer purely cardiac.

To return to the consideration of this symptom as it is presented to our notice by patients. In some cases, dyspnoea is objective—that is to say, we notice that the activity of respiration is increased, although the patient perhaps makes no complaint on this score. At other times shortness of breath is a prominent complaint, and here, as a rule, we find that dyspnoea is considerable. For patients do not commonly themselves complain of this symptom until dyspnoea becomes pronounced. It is important to determine whether dyspnoea occurs as the result of exertion, change of posture, excitement, indigestion of food or other definite external influences, or whether its development is apparently spontaneous. In the former case the development of dyspnoea on relatively slight provocation argues a certain degree of cardiac insufficiency which may not be incompatible with fair health, if the causes of dyspnoea can be avoided. On the other hand, spontaneous dyspnoea is a sign of more serious impairment of the heart's functional capacity.

Dyspnoea, though a most valuable symptom, cannot alone be trusted to give us reliable indication of failure of the heart. For muscular exertion may occasion dyspnoea and increased rapidity of the pulse in cases of cardiac enlargement where dilatation is satisfactorily compensated by hypertrophy. The development of dyspnoea on relatively slight provocation should, however, lead us to suspect that rupture of compensa-

tion has commenced. But the determination of the precise period at which failure commences is rarely possible, owing to the gradual manner in which the transition is effected. Signs of stasis in the lungs and portal system are among the earliest indications of insufficiency of the heart.

Orthopnoea is the condition in which the patient is compelled to sit upright, the reclining posture giving rise to severe dyspnoea. The relief obtained by this means is due probably to more than one cause. In the first place, in consequence of the erect position, the liver and abdominal viscera sink downwards, owing to the force of gravity, and the inspiratory descent of the diaphragm is thereby facilitated. Moreover, as Corvisart suggested, the vertical position impedes the flow of blood from the vena cava inferior into the heart, and reduces the engorgement of the right heart and pulmonary vessels. Again, when the patient sits up, the accessory muscles of respiration can act more freely, and are less hampered by friction, than when he lies on his back. Orthopnoea has the same significance as a high degree of dyspnoea. But, as Traube pointed out, orthopnoea is a more favourable symptom than the apathetic state in which some cardiac patients sink down in bed, for the former posture argues a degree of vigour which is wanting in the latter case.

Paroxysmal attacks of dyspnoea or cardiac asthma are comparatively uncommon, and are not specially characteristic of any particular form of heart disease. This condition is believed to depend on a sudden parietic relaxation of the left ventricle, but its pathology is still somewhat doubtful.

Palpitation is a subjective sensation and possesses much less diagnostic value than dyspnoea. When a patient is conscious of the heart's pulsation he is said to have palpitation. Many persons compare the sensation to the fluttering of a bird; others say that it is accompanied by a choking feeling in the throat. The sense of palpitation may be combined with violent action of the heart, that can be recognised by the physician, but at other times no external evidence of cardiac disturbance can be discovered. Moreover, the forcible pulsations of a greatly enlarged heart are often unassociated with any subjective sensations on the part of the patient. The pulse is usually, but not invariably, increased in frequency, and the rhythm of the heart's

action is generally to some extent deranged.

Palpitation is of common occurrence in all organic affections of the heart, especially when failure is threatened or actually established, but it is also a very common symptom in cases where there is every reason to believe that the heart is healthy. In either case the sensation is always more or less paroxysmal in character. Emotional, gastro-intestinal, uterine, and other impressions may cause palpitation in a reflex manner. Palpitation in organic affections is, generally speaking, a sign of cardiac debility, and in case of severe dilatation it may be an expression of disordered action of the cardiac ganglia, in consequence of the stretching to which the muscular parietes are subjected. A sense of palpitation is at times connected with attacks of extremely rapid action of the heart, the pulse rising as high as 200, an uncommon affection known as "tachycardia." No constant relation exists between palpitation and dyspnoea.

Pain.—Sudden paroxysmal attacks of agonising pain in the region of the heart, associated with a sense of impending death, and with other symptoms, may complicate various affections of the heart, and are further considered under the head of ANGINA PECTORIS (*q.v.*). Apart from anginal attacks, cardiac patients seldom suffer from severe pain, though a sense of oppression or pressure about the heart is very common. When præcordial pain is present it is apt to radiate to the arms, and especially to the left arm.

Rheumatic pains about the chest are sometimes incorrectly referred to the heart. In some cases there is marked tenderness on pressure or percussion, over the whole cardiac area, but localised painful spots may be sometimes discovered. Whether these tender points are really due to any lesion of the cardiac nerves is very doubtful. In some instances the pain and tenderness appears to be very superficial, and to depend on some affection of the intercostal nerves.

Pulse.—The pulse of dilatation and cardiac insufficiency is weak, small, frequent and generally of low tension, these characters being developed at an earlier date when the left ventricle is primarily affected. The presence of extensive arterial degeneration or chronic renal disease may modify the pulse of dilatation, a relatively high arterial tension persisting even when the cardiac debility is considerable. When dilata-

tion is more or less compensated by hypertrophy, the pulse may give no indication of disease.

The rapidity of the pulse, speaking generally, is increased in all cases of cardiac debility, though exceptions to this rule are not wanting. In the terminal stages a frequent pulse is almost invariable.

Cardiac Rhythm.—In most cases of cardiac insufficiency the heart and pulse exhibit some degree of irregularity in the force and volume of the individual beats, as well as in the intervals separating them. This condition has been described as *arrhythmia*.

Curious modifications of the heart's rhythm are sometimes noticed. In one form the beats run in pairs in regular succession, the second beat being usually weaker than the first, and being followed by a longer interval (*pulsus bigeminus*). In these cases the second weaker beat may fail to reach the wrist altogether, and what was at first regarded as a very infrequent pulse, proves, on auscultation of the heart to represent only half the number of contractions of the ventricle. At times a triple rhythm occurs where three beats follow each other at regular intervals, and are then succeeded by a pause (*pulsus trigeminus*). To these and other perversions of rhythm the term *allorhythmia* has been applied. *Allorhythmia* and *arrhythmia* have been ascribed with much probability to derangement of the intrinsic nerve apparatus of the heart, but the possibility of the nervous affection being central in some cases where no other evidence of cardiac disorder is present must not be lost sight of.

In most cases of insufficiency of the heart, the occurrence of *arrhythmia* or *allorhythmia* is of bad omen, and is significant of profound dilatation, with or without structural changes in the myocardium, the irregularity being due possibly to disordered action of the intra-cardiac nerve ganglia, consequent upon stretching of the muscular walls. This statement, however, must be made with considerable reservation, as cases of extreme cardiac failure may run a fatal course without any important alterations of the heart's rhythm, and, on the other hand, a considerable degree of *arrhythmia* or *allorhythmia* is not incompatible with complete integrity of the heart. The action of certain drugs, especially digitalis, must be mentioned as a relatively common cause of perverted cardiac rhythm.

Patients suffering from severe dilatation and insufficiency of the heart sooner or later present signs of **Venous Congestion and Dropsy**. The skin of the face and extremities becomes livid and cyanosed, the veins of the neck are distended and exhibit slight oscillations, or even systolic pulsation, in cases where tricuspid incompetence has developed.

The effects of venous stasis are felt at an early date by the lungs and abdominal viscera.

Lungs.—Passive congestion of the lungs, as we have already pointed out, is one of the first consequences of cardiac insufficiency, and is manifested by characteristic symptoms, of which dyspnoea is the chief. Accentuation of the second sound in the pulmonary artery is justly regarded as a valuable sign of high pressure in the vessels of the lungs, but it must be remembered that it also shows that the vigour of the right ventricle is not seriously impaired. For when failure of this chamber occurs, the accentuation of the second sound may disappear, although the pulmonary stasis is as great as ever. This possible source of fallacy should be borne in mind.

Congestion of the vessels is very apt to lead to serous transudation into the air sacs, which greatly aggravates the existing dyspnoea.

The pathology of *œdema of the lungs* is not altogether clear. Cohnheim believed that failure of the left ventricle with relatively unimpaired power of the right ventricle were the conditions necessary for its production. It is doubtful, however, whether this view expresses the whole truth. Slight degrees of pulmonary œdema may be quickly recovered from, but the presence of this complication is to be regarded as a grave symptom, partly as showing the existence of serious mechanical hindrance to the circulation, and partly on account of the restriction of the aerating surface of the lung which it involves.

Liver.—The low pressure at which the blood of the portal vein enters the liver explains the great tendency to passive congestion and enlargement displayed by this organ in response to any condition that impedes the entry of blood into the right auricle. When cardio-pulmonary stasis occurs the liver speedily becomes enlarged and tender, and, if there be leakage at the tricuspid orifice, expansile hepatic pulsation may be detected. Inasmuch as prolonged passive congestion is wont to cause induration and contraction, an enlarged

liver may gradually decrease in size, although the venous stasis persists, and the typical nutmeg change, or congestive atrophy of the liver, is then developed. This condition of the liver may be accompanied by a slight degree of jaundice, owing probably to passive duodenal catarrh. It is important to remember this fact, lest the gradual diminution of hepatic enlargement should give a wrong impression.

Spleen.—Enlargement of this organ can sometimes be recognised by palpation, but in the later stages the spleen is usually contracted.

Kidneys.—Congestion of the kidneys is shown by the excretion of scanty, high-coloured urine of high specific gravity, containing a small quantity of albumen, and often depositing copious urates on standing. A few hyaline casts may occasionally be detected on microscopical examination.

The symptoms of gastro-intestinal and cerebral congestion have been already incidentally referred to—constipation, diarrhoea, hæmorrhoids, vomiting, mental dulness and apathy.

Dropsy of the subcutaneous tissue, beginning in the lower extremities, but involving at an early date parts like the scrotum and eyelids where the skin is lax, is often followed, and is occasionally preceded, by transudation into serous cavities, such as the pleura or peritoneum. Dropsy of the pericardium is much less common, and is generally developed at a later stage.

The pathology of cardiac dropsy cannot be said to be satisfactorily explained by increased pressure in the veins alone, though this is undoubtedly an important factor. It is probable that a direct influence must be attributed to alterations in the chemical composition of the blood, dependent on the malnutrition of cardiac disease.

PHYSICAL EXAMINATION OF THE HEART.—The physical signs of dilatation and hypertrophy may be very pronounced, but from various causes this is by no means invariably the case. The most reliable information is derived from palpation and percussion.

When hypertrophy is well-marked, the præcordial region may show evident bulging, and the heart's pulsations may be unduly visible. Palpation shows that the impulse is forcible, heaving, and often diffused.

When dilatation preponderates over hypertrophy the impulse is weak, undulating, or impalpable. The præcordial

dulness is increased in cases of enlargement of the heart, whether this be due to hypertrophy or dilatation.

In the examination of the heart gentle percussion which determines the area of absolute cardiac dulness—i.e., the extent of the heart's surface uncovered by lung—gives better results than attempts to map out the actual size of the organ by forcible percussion. A careful cultivation of the sense of resistance, coupled with light percussion, is of the utmost importance in estimating slight degrees of cardiac enlargement. The elasticity of the sternum and its tendency to conduct vibrations to the neighbouring parts of the lungs, are so great that at times we may feel the pulsations of an hypertrophied right ventricle beneath this bone, and may yet be unable to detect any corresponding dulness on percussion. If, in such cases, Guttman's suggestion be adopted, and the left hand be firmly pressed on the upper part of the sternum, while percussion is made on the first finger placed over the lower end, we may sometimes succeed in damping the vibrations of the sternum, and in eliciting the dulness of the subjacent heart. Emphysema of the lungs and retraction of their anterior margins are also sources of error, and the presence of these conditions must be carefully taken into account.

In the presence of emphysema, extensive cardiac enlargement may be entirely masked by the resonance of the distended lungs overlapping the heart. Retraction of the edge of the lungs, more particularly the left, uncovering the heart, is very common in cases of chronic phthisis, and may simulate cardiac hypertrophy and dilatation, owing to the increased surface of the heart brought into contact with the chest wall.

The existence of auscultatory signs of phthisis in the corresponding lung with evidence of flattening and impaired movement of that side of the chest will generally prevent mistakes. At times the heart is evidently dislocated to one or other side, and no actual increase in the area of præcordial dulness exists. When, as sometimes happens, retraction of the lung occurs without falling in of the thoracic walls, difficulties are more likely to arise. In such cases the absence of the symptoms and consequences of cardiac disease will point to the conclusion that the enlargement of the heart is only apparent.

Auscultation usually gives little assistance in the diagnosis of hypertrophy and

dilatation, except in a negative way, though the absence of characteristic murmurs in a case of enlargement of the heart is of much importance, as tending to show that the efficiency of the valves is unaffected. It will be seen in the section on diseases of the valves that the complete absence of murmurs is not incompatible with the presence of a valvular lesion under certain circumstances, but speaking generally, the fact that no murmur is audible has the significance above stated. At times the ear may detect the impulse of a large, weak heart, which is scarcely to be recognised by palpation, and here auscultation (with a rigid stethoscope) possesses a direct value. The sounds of an hypertrophied heart are clear and distinctly audible, but the first sound is apt to be somewhat duller than usual.

When dilatation predominates, the first sound is shorter, sharper, and of higher pitch than in health, and resembles the normal second sound.

The second sound is not altered in either condition, except as the result of increased tension in the aorta or pulmonary artery.

Physical Signs of Enlargement of the Left Ventricle.—The apex beat is displaced downwards and to the left, and the cardiac dulness is increased in the same direction—that is to say, in its longitudinal or oblique axis. With hypertrophy the apex beat is strong and heaving, whereas the impulse of a dilated heart is weak and diffused, or may be quite imperceptible.

In hypertrophy of the left ventricle the heart sounds are louder at the apex than over the right ventricle.

Physical Signs of Enlargement of the Right Ventricle.—The apex beat is in the normal position, or slightly displaced outwards. The cardiac dulness is increased to the right, and not infrequently somewhat to the left also. Hypertrophy is shown by forcible pulsation over the lower end of the sternum and in the epigastrium, the heart sounds being louder over the right ventricle than at the apex.

We have seen that extreme dilatation of the ventricles may lead to incompetence of the auriculo-ventricular valves, hence a systolic murmur in the mitral or tricuspid area is not uncommonly developed in cases of severe dilatation.

If the patient should come under observation at this stage, it may be impossible at first to decide whether the valvular incompetence is absolute or

relative—that is to say, whether it is due to structural changes in the curtains, or to simple dilatation of the orifice. The course of the disease will often, but not always, solve the question. Great variations of intensity, or still more, a complete disappearance of the murmur as the heart's power is gradually restored, point to a relative incompetence of the valve.

The co-existence of a marked degree of enlargement with a weak, small pulse that cannot be accounted for by any valvular defect or other mechanical impediment is very significant of dilatation. Disappearance of the apex beat points in the same direction if the existence of emphysema and pericardial effusion can be excluded.

It may again be remarked that dilatation and hypertrophy are always associated in varying proportions, and that when we speak clinically of hypertrophy or dilatation being present, we mean that one of these conditions predominates.

The existence of enlargement of the heart without disturbance of the circulation argues hypertrophy; enlargement with evidence of circulatory derangement implies dilatation.

PERCY KIDD.

HEART, FATTY DISEASE OF.

—The clinical designation “fatty heart” includes two different forms of disease. In the first and most important variety a fatty degeneration or metamorphosis of the muscular fibres is the essential process. In the second, known as fatty infiltration, the quantity of sub-pericardial fat is increased in quantity. These conditions require separate consideration.

Fatty Degeneration of the Heart.—

Symptoms and Diagnosis.—The symptoms of fatty degeneration are very uncertain; indeed, this affection can only be suspected when it gives rise to dilatation and insufficiency of the heart; consequently dyspnoea, palpitation, a small irregular pulse, and other symptoms of dilatation are the indications to which we must look in the first instance.

It should be borne in mind that extensive fatty degeneration may exist without giving rise to any disturbance of the heart's functions, and that there is no essential relation between a fatty change and cardiac derangement. In the absence of signs of dilatation it is quite impossible to diagnose fatty degeneration of the heart. The presence of conditions that

are known to predispose to fatty degeneration may suggest the possibility of the lesion being present in a case characterised by dilatation and weak action of the heart, but it is seldom feasible to arrive at more than a probable diagnosis. A pulse falling to 50 or even lower, attacks of angina pectoris and cardiac asthma, Cheyne-Stokes' respiration, a tendency to syncope and sudden death, may be occasionally met with in cases of fatty degeneration of the heart, but these symptoms are not specially characteristic of this condition, and therefore possess only a relative value. The existence of arcus senilis is no longer believed to have any special relation to fatty changes in the heart.

Pathology of Fatty Degeneration.—It is customary to distinguish various forms of degeneration—parenchymatous, granular, and fatty—but it is probable that these are only different stages of one and the same process.

The morbid change in each instance consists in a transformation of the protoplasm of the muscular fibres, which lose their normal striation in varying degrees, the muscle fibres and nuclei becoming filled with albuminous and fatty granules.

Parenchymatous degeneration of the myocardium may exhibit all stages, from a mere reddish grey discoloration, or “cloudy swelling,” to an advanced condition of fatty degeneration, in which the substance of the heart is soft and yellowish, and exudes an oily fluid on pressure. In the common forms of fatty degeneration the deeper or sub-endocardial layers of the muscular tissue are marked with small yellowish patches and lines, the change being usually most pronounced in the case of the musculi papillares and trabeculae of the ventricles, though a similar condition may be widely diffused through the heart's substance.

In some cases it is thought that acute granulo-fatty changes in the muscular fibres are to be regarded as the results of inflammation, and the term “parenchymatous myocarditis” is then applicable. But, on the other hand, it is equally probable that an acute myocardial affection may be due to a parenchymatous degeneration. Acute myocarditis characterised by cellular infiltration of the intermuscular planes is of very rare occurrence.

Slight degrees of fatty degeneration are probably capable of complete removal, but our knowledge of the extent to which repair is possible in this and

allied conditions is mainly conjectural. Fatty degeneration occasionally leads to rupture of the heart and to fatal hemorrhage into the pericardium, the left ventricle being nearly always the seat of spontaneous rupture.

Etiology.—The cause of fatty degeneration is to be sought in a deficient supply of duly oxygenated blood to the muscular tissue of the heart. This may be the result of changes in the blood, as in anæmia (especially "pernicious" anæmia), phosphorus poisoning, specific fevers, the puerperal state, and long-continued pyrexia of any kind, or it may be due to any condition that interferes with the circulation through the coronary or nutrient arteries of the heart. Defective coronary circulation may be caused either by local obstruction or by failure of the heart's driving power. Thus, fatty degeneration may be the consequence of atheroma of the root of the aorta, involving the orifices of the coronary arteries, as well as of similar disease of these vessels themselves, or again it may be due to cardiac insufficiency resulting from any cause. Fatty degeneration may lead to dilatation, and therefore indirectly to hypertrophy, but more often cardiac enlargement is the primary condition, and granulo-fatty changes are only secondary effects. Fatty degeneration of the heart has no connection with general obesity.

Fatty Infiltration or deposit consists in an overgrowth of the sub-pericardial fat, which is normally most abundant along the auriculo-ventricular sulci, and in the course of the larger branches of the coronary arteries, over the right ventricle and at the apex of the heart.

Symptoms and Diagnosis of Fatty Infiltration.—The symptoms are practically the same as those of fatty degeneration, and depend upon the degree of dilatation and cardiac insufficiency present in individual cases. Attacks of angina and cardiac asthma may also occur in this form of fatty heart. It is doubtful how far dyspnoea is due to the condition of the heart in cases where little evidence of cardiac dilatation exists. It is probable that a tendency to shortness of breath is a direct consequence of obesity, extra work being thrown upon the heart by the great decrease of bodily weight. The occurrence of hypertrophy in fat persons may be thus explained in uncomplicated cases, but obesity is apt to be associated with other conditions which are known to cause hypertrophy, such as chronic renal

disease, arterio-sclerosis, or degenerative changes in the heart's muscle.

The *diagnosis* of this affection is even more uncertain than that of fatty degeneration. Fatty infiltration may be suspected in a fat person with a weak dilated heart. Physical examination is often greatly impeded in such cases, especially in women in whom the excessive development of the panniculus adiposus and of the mammary gland may render accurate percussion almost impossible. The position of the apex beat may assist in the determination of cardiac enlargement. In any case, however, diagnosis is merely a question of probability. Such cases occasionally terminate with the usual symptoms of dilatation and cardiac failure, or the patient may die suddenly from syncope.

Pathology.—In cases of fatty infiltration, the heart is buried in an envelope of fat, and the muscular substance seems to be thinned out and encroached upon by the adipose growth, which may extend deeply into the wall of the heart between the muscular fibres.

Microscopical examination reveals a fatty infiltration in the form of large oil globules separating the muscular fibres, these latter showing little or no qualitative change. The atrophy of the muscular wall has been attributed by some authors to the pressure of the fatty covering, but there can be little doubt that the muscular atrophy is not the result of the fatty growth. It is possible that the muscular change is the primary one, and is followed by an overgrowth of fat, just as in the case of the voluntary muscles in pseudo-hypertrophic muscular paralysis. On the other hand both changes may be the result of a common cause.

Etiology.—Fatty infiltration is commonly an expression of general obesity, but at times an accumulation of fat on the surface and in the substance of the heart occurs in wasting diseases like cancer and phthisis. Many fat people suffering from cardiac symptoms, and thought to be the subjects of "fatty heart," are found on post-mortem inspection to have greatly dilated and hypertrophied hearts without any excessive development of fat. It is not unusual to discover an excessive degree of fatty overgrowth on making a post-mortem examination in cases where no cardiac symptoms whatever were manifested during the patient's lifetime. It is a moot point whether plethora, resulting from excessive ingestion of food, is or is not to be credited with some

influence in the production of cardiac hypertrophy in cases of this description.

Prognosis.—The prognosis, whether in the case of fatty degeneration or fatty infiltration of the heart, turns on the pathology of the individual case. When the cause can be removed, as, for example, in some forms of anæmia and obesity, recovery is possible. When degenerative changes depend on local vascular causes we cannot expect repair, but when cardiac failure is the efficient cause of degeneration considerable relief may be obtained if the contractibility of the cardiac muscle can be restored.

Treatment.—The treatment of both forms of fatty heart, when they can be recognised, must be directed to improving the power of the heart and diminishing the dilatation of its cavities. In other words, the treatment is that of cardiac disease in general, and consists in the administration of digitalis, strophanthus, strychnine, ether, and other cardiac tonics, with a moderate amount of alcohol, rest, and a light nutritious diet. Direct treatment by means of drugs is only required when signs of cardiac failure are present. When these symptoms have disappeared or have been mitigated, we may endeavour to improve the nutrition of the cardiac muscle by cautious and gentle bodily exercise. Special attention must be paid to the regular evacuation of the bowels.

Where obesity exists, treatment must be judiciously directed to the reduction of this condition, and should include a regulation of the diet, gentle and regular exercise, and other suitable measures. In all cases of this description a rational general treatment is of the first importance. The patient should lead a quiet, regular life, and should be warned to avoid excitement and sudden exertion as far as possible. Moderation in the use of alcohol and tobacco must be particularly insisted upon. (*See EXERCISE*).

PERCY KIDD.

HEART, FIBROID DISEASES OF THE (including Cardiac Aneurysm, Chronic Myocarditis, Fibrous Transformation).—A fibrous change in the walls of the heart, either diffused or circumscribed, the latter variety often leading to the formation of a cardiac aneurysm.

Symptoms.—The symptoms of this affection are almost as uncertain as those of "fatty heart." It has been clearly demonstrated that a considerable degree of fibrous transformation of

the heart's muscle is not incompatible with perfect functional activity of the organ. But cases of serious dilatation and insufficiency have been recorded in which limited fibroid disease of the ventricle was the only morbid change discovered to account for the cardiac failure after death.

The positive symptoms of cirrhotic changes in the myocardium are those of cardiac affections in general—dyspnoea, palpitation, a sense of constriction, signs of passive congestion of the lungs, abdominal viscera and systemic veins, with or without dropsy. The immediate cause of these symptoms is to be found in dilatation and insufficiency of the heart. In addition to the above signs of disturbance of the circulation, common to all organic affections of the heart, there are certain symptoms that have been more particularly connected with fibroid disease. Attacks of cardiac asthma and of angina pectoris, a tendency to syncope, and a marked slowing of the pulse, which may fall to 30, or even lower, have been noted in some cases.

Marked irregularity of the force and rhythm of the pulse is not uncommonly present, especially where dilatation exists. Some German authors assign great diagnostic importance to this condition. Ruehle attributes the arrhythmia to the failure of the left ventricle, which is the chamber usually affected with fibroid disease. Riegel goes still farther, and maintains that arrhythmia may often be present before any symptom of insufficiency has arisen, and also that when dilatation and failure of the heart have yielded to treatment, arrhythmia may, nevertheless, persist as the sole cardiac symptom, and in such cases is almost a pathognomonic sign. This author explains the arrhythmia by the interference with the cardiac ganglia and nerves, caused by the fibrous disease in cases where the lesions are widely diffused. If this point should be established, it will constitute a valuable addition to our meagre stock of symptoms. It is doubtful whether Riegel's explanation would apply to cases where the morbid change is confined to the apex of the left ventricle, as is so often the case. Arrhythmia is a common symptom in cardiac dilatation from whatever cause, and when once this condition has developed, no special diagnostic value can be attached to the presence of arrhythmia.

Aneurysms of the heart frequently form as the result of circumscribed

fibroid disease, and may rupture into the pericardial cavity and cause sudden death; or they may open up communication between the various chambers of the heart, and occasion more or less disturbance of the circulation; but it is doubtful whether they are ever accompanied by any special symptoms that enable us to recognise their presence.

One of the most clearly established clinical characteristics of fibroid disease is the fact that death is very apt to occur in a sudden apoplectic form manner, and this not only in cases with actual cardiac symptoms, but in persons that were apparently in perfect health. This occurrence has never been satisfactorily accounted for.

It is not improbable that the sudden end of patients suffering from fibroid disease is due, in some cases at least, to an attack of angina pectoris. The frequency with which lesions of the coronary arteries are found in both affections lends some support to this view.

Quite recently the writer had the opportunity of observing such a case. A woman who presented signs of hypertrophy of the left ventricle, had suffered for some time from anginal attacks of moderate intensity. In one of these attacks she died suddenly. At the necropsy, fibroid disease of the apex of the left ventricle, atheroma of the coronary arteries, and cirrhosis of the kidney were found. The left ventricle was hypertrophied and dilated.

In exceptional cases sudden death has been the result either of rupture of the heart, an event especially likely to happen when cardiac aneurysm exists, or of embolism of one of the main coronary arteries, the latter condition being exactly analogous to ligature of one of the coronary arteries, which, as Cohnheim showed, speedily leads to permanent diastolic arrest of the heart's action. Cases of cardiac cirrhosis may terminate suddenly with embolism of the brain, or death may occur with the ordinary symptoms of cardiac failure, asthenia, venous stasis and dropsy.

Diagnosis.—It is very doubtful whether it is possible to distinguish this affection from other forms of myocardial disease. In a given case of dilatation and hypertrophy of the heart, associated with generalised atheroma of the arteries, the presence of fibroid disease may be suspected when extrinsic causes of cardiac enlargement can be excluded. Evidence of past syphilis would perhaps somewhat strengthen this suspicion. But when

efficient causes of hypertrophy and dilatation, such as lesions of the valves or renal disease co-exist, the diagnosis of fibrous changes in the heart is impossible.

When dilatation gives rise to relative incompetence of the auriculo-ventricular valves, with a systolic mitral, or tricuspid, murmur, the existence of fibroid disease may be easily overlooked, and the state of the heart may be attributed to a primary affection of the valves. The diagnosis of cardiac aneurysm can rarely be more than conjectural.

Pathology.—As already stated, fibroid disease of the heart may be either **diffused** or **circumscribed**. The former variety, described by Dr. Quain as connective tissue hypertrophy, occurs in dilated and hypertrophied hearts, the thickening being due to a diffuse overgrowth of the perimysium. Possibly this fibrous hyperplasia may be connected with congestion of the heart, to which Sir William Jenner called attention long ago. Great distension of the cavities of the heart must impede the return of blood by the coronary veins, and passive congestion of the viscera is known to lead to a certain degree of fibrous thickening. A diffuse intermuscular growth of connective tissue would have the effect of interfering with the heart's contraction, and would predispose to dilatation. Further investigation is required to clear up the pathology of this condition.

In the **circumscribed** form, patches of whitish, tough, fibrous tissue are found in the myocardium, especially at the apex, but they may be met with in other parts of the left ventricle. When the right ventricle is affected, the disease commonly appears to have spread from the left ventricle. These patches may involve the whole thickness of the cardiac wall, but not unfrequently they are most marked in the middle layers of the myocardium. Occasionally they are imbedded in the muscular tissue, and are only discovered on making sections of the heart's wall.

Fibrous thickening of the papillary muscles and endocardium is very common in all cases of high intra-cardiac pressure, but this condition must not be confounded with the present affection.

Microscopical examination shows that these patches consist of a dense fibrous tissue which, as a rule, is very poorly supplied with nuclei, though small areas of cellular infiltration may be seen in places, especially towards the margins.

Muscular fibres are generally absent altogether where the sclerotic process is most advanced, but a few isolated atrophic fibres, remains of blood pigment, or extravasated blood corpuscles, may be sometimes recognised among the scar-like tissue.

A varying degree of thickening of the perimysium is usually present at the margins of fibrous tracts, and may extend widely beyond the primary seat of disease. The intervening muscular tissue, as a rule, presents a healthy appearance, though some few fibres may exhibit granulo-fatty degeneration. Where the walls of the heart have undergone this transformation, they are usually somewhat thinned out, the fibrous parts being depressed below the level of the surrounding muscular tissue. The effects of this change on the functional activity of the heart vary considerably. When the cirrhosis is limited and of slight degree, it may give no evidence of its presence; but a more extensive transformation of the myocardium not unfrequently causes a marked degree of general dilatation and hypertrophy, the former as a rule predominating. The occurrence of general dilatation is to be explained partly by the extension of the cirrhotic change beyond the confines of the primary disease, and partly by the interference with the intrinsic nerve structures which the fibrous growth involves.

In certain cases the cirrhotic tissue gradually yields at some point to the internal pressure of the blood and a partial dilatation or **aneurysm of the heart** is produced. This represents the usual method of development of cardiac aneurysms.

Circumscribed thickening and adhesion of the pericardium are very commonly met with. The pericardial cavity may be entirely obliterated, but in general the adhesion and thickening attain their highest development over the fibroid area, and are usually confined to this point. Thrombosis is extremely common, and is usually limited to the portion of the ventricle corresponding to the myocardial disease.

The pathology of this disease has been the subject of much discussion. Fibrous induration of the myocardium may be a sequel of pericarditis or endocarditis, the inflammatory process being propagated directly to the muscular substance. In such cases which merit the term **chronic myocarditis**, the morbid process is always more or less limited to the

sub-pericardial or sub-endocardial layers, and does not give rise to the extensive cirrhotic changes that have just been described.

Until recent times the origin of **fibrous transformations** of the myocardium was generally attributed to a primary inflammation of the muscular tissue, and the disease was styled chronic interstitial myocarditis. It is now, however, generally recognized that this is not the usual course of events. The observations of Weigert and Huber have shown that in many, probably in most, cases fibroid induration or degeneration is closely associated with **obstruction of the coronary arteries**. The vascular obstruction may be partial or complete, and may involve one of the main coronary arteries or may be confined to one of their finer twigs. Moreover, owing to the great frequency with which atheroma attacks the root of the aorta, the orifices of the coronary arteries are very liable to become obstructed. Narrowing of these vessels, whether it be due to arteriosclerosis, endarteritis obliterans, thrombosis or embolism, causes anæmia and necrosis of the muscular bundles supplied by the corresponding arterial branch. When the occlusion is sudden and complete—an event more likely to occur in the case of embolism—infarction and coagulative necrosis of the myocardium may be followed by rapid softening and rupture of the heart's wall. In other instances a reactive hyperplasia of the connective tissue is produced. In the more ordinary form, where obstruction is gradual, atrophy of the muscular substance is also associated with fibrous changes. It is sometimes difficult to decide whether the connective tissue found in the cardiac wall is the result of a new formation or represents merely the normal interstitial framework stripped of the proper muscular elements; but the relative proportions of muscular atrophy and fibrous development are liable in all probability to considerable variations. In either case, however, the primary lesion is a vascular one, necrosis or atrophy being followed by a species of secondary scar-formation. This process is strictly analogous to the development of cicatrices in the kidney as the result of infarction.

Fibrous transformation, however, is not an invariable result of narrowing of the coronary arteries, for this condition may induce a fatty degeneration of the muscular tissue, and in some cases is

followed by no definite change whatever. These different results possibly depend on the degree of obstruction, as well as on the amount of collateral circulation that is developed. From Hyrtl's researches we know that the larger branches of the coronary arteries do not inosculate, but the result of injections carried out by Wickham Legg and S. West show that a considerable degree of anastomosis nevertheless exists; and this is probably effected by communications between the finer arterial branches. Complete occlusion of the coronary arteries, unless collateral circulation be speedily effected, leads to necrosis, with its results, softening or cicatrization. When obstruction is incomplete, the effects are more uncertain. Slight degrees of narrowing may have no injurious effects, whereas further restriction of the circulation may give rise to granulo-fatty degeneration, or to atrophy, necrosis and fibrous changes.

The predilection shown by fibrous transformation for the apex and neighbouring parts of the ventricles—*i.e.*, the distal points of the coronary circulation—the special liability to disease of the middle layers of the myocardium, the limited distribution of the change, and, lastly, the frequent association with disease of the coronary arteries, accord better with the theory of a vascular origin than with the hypothesis of a primary inflammation or chronic myocarditis. The fact that pericardial adhesions are so often strictly confined to the area of the fibroid patch is also opposed to the notion that the lesion is primarily pericardial.

The *etiology* of fibroid disease is consequently to a large extent the same as that of affections of the coronary arteries and of arterio-sclerosis in general.

Diffuse atheroma is known to be related to gout, syphilis, alcoholism, excessive muscular work and senile changes. The male sex is specially liable to arterial degeneration, and also to fibroid disease. Syphilitic gummata have occasionally been found in the heart's walls, and possibly some of the comparatively rare cases of chronic interstitial myocarditis may represent sequelæ of gummatous processes. Endarteritis obliterans of the coronary arteries has been ascribed to syphilis.

Treatment.—The treatment is that of cardiac disease in general, and the remarks made in the article on **FATTY DEGENERATION OF THE HEART** (*q.v.*) are applicable here also. When insuffi-

ciency of the heart is pronounced, digitalis should be given cautiously; but the effect of this drug must be carefully watched, as it sometimes increases the irregularity and weakness of the pulse.

When the pulse is very infrequent, digitalis is contra-indicated. Other cardiac stimulants, such as ether, ammonia, strychnine, alcohol, are sometimes of more service than digitalis, and may be more freely and safely administered. A course of iodide of potassium should be tried if the patient has suffered from syphilis.

Anginal attacks must be treated on the general principles described in the article on **ANGINA PECTORIS** (*q.v.*).

Cardiac asthma is often benefited by stimulant remedies like ether and ammonia, but at times injections of morphine alone give relief.

PERCY KIDD.

HEART, HYPERTROPHY AND DILATATION OF THE, FROM OVERSTRAIN.

—The influence of excessive bodily exercise on the heart is discussed in a general manner in the article on **DISEASES OF THE MUSCULAR WALLS OF THE HEART** (*q.v.*), but the importance of this relation is so great that the subject requires separate consideration.

It has long been known that the hearts of stags that have been hunted are often found to be enormously hypertrophied, and similar observations have been made in the case of race-horses. The comparatively recent researches of Da Costa, Myers, and other authors have clearly shown that the human heart is also liable to hypertrophy and dilatation under analogous conditions.

Instances of marked insufficiency of the heart, presenting the usual signs of hypertrophy and dilatation, are not unfrequently met with in which none of the ordinary causes of cardiac enlargement can be discovered. That is to say, the most careful investigation, both clinical and anatomical, shows a complete absence of disease of the muscular walls or valves of the heart, of arterial degeneration, renal disease, and emphysema or other chronic affection of the lungs. In many cases a review of the conditions under which the patients have lived establishes the fact that their occupation involved prolonged and heavy muscular work.

The *symptoms* of overstrain do not differ from those of dilatation and hypertrophy resulting from other causes. All

degrees of insufficiency or failure of the heart may be observed in different cases.

The *course* of the disease may be progressive, terminating gradually with signs of venous stasis, dropsy and exhaustion; or death may occur more suddenly as the result of embolism or other accidental complications. In other instances temporary improvement may ensue, and complete recovery is not impossible if the affection be recognized at an early stage.

The *diagnosis* turns partly on the presence of dilatation and hypertrophy, without any evidence of valvular lesion or other recognized causes of cardiac enlargement, and partly on the laborious nature of the patient's occupation. As a rule, the exclusion of some degree of renal or myocardial disease is extremely difficult, and often impossible, and when, as sometimes happens, more than one of these conditions is present, the diagnosis is very uncertain. Enlargement of the heart occurring in a young man engaged in very heavy work may, with a considerable degree of probability, be ascribed to overstrain when no other condition favouring hypertrophy and dilatation can be recognized.

Pathology.—The cardiac enlargement is commonly most pronounced in the case of the left ventricle, but some degree of general hypertrophy and dilatation is almost always present. This fact strongly supports the connection between bodily labour and enlargement of the heart, for, as stated in the article on the DISEASES OF THE MUSCULAR WALLS OF THE HEART (*q.v.*), the effects of muscular exercise are primarily exerted on the left ventricle.

It is probable that the initial change is a yielding of the left ventricle to the increased arterial pressure, dilatation being rapidly followed by an amount of hypertrophy that is liable to considerable variation. When prolonged and excessive demands are made on the activity of the heart, the development of a moderate degree of hypertrophy must be beneficial, as tending to counteract the effects of dilatation. But in the cases now under consideration, the hypertrophy which results is insufficient for this purpose, and it would seem that such hearts were not originally possessed of the average power of resistance or reserve force.

Ætiology.—An adequate supply of healthy blood to the cardiac muscle is a condition necessary for the development of hypertrophy, and Dr. Allbutt has par-

ticularly emphasized this point by insisting upon the influence of bad feeding in the causation of overstrain of the heart. This affection, as he shows, has been comparatively rarely met with among the wealthier classes, most of the cases having occurred among blacksmiths, porters, and workers at various trades, in whom the effects of heavy manual work and insufficient food are more apt to be combined. Cardiac overstrain is very seldom met with in the female sex. Da Costa, in his observations on soldiers, found that this condition of dilatation and hypertrophy was preceded in several instances by symptoms of what he calls "irritable heart," a subject which is more fully considered in the article on NEUROSES OF THE HEART (*q.v.*).

Treatment.—Rest is indispensable, and is of more value than any other measure. The patient's occupation must be modified or changed so as to allow, as far as possible, of the removal of the cause of the disease. Digitalis should be exhibited only when signs of cardiac failure are manifested, and its effects must be carefully watched. If irregularity of the heart's action appear, or become aggravated, the drug must be discontinued. Ether, ammonia, strychnine, and other cardiac tonics may be used under the same circumstances, and may at times be advantageously combined with digitalis. Da Costa recommends aconite when hypertrophy is commencing. It is open to doubt, however, whether hypertrophy *per se* requires any special treatment beyond rest. The diet should be moderate, but nutritious, and alcohol in small quantities may be allowed. The importance of a regular action of the bowels cannot be too much insisted on.

The treatment of special symptoms must be conducted on appropriate general principles. PERCY KIDD.

HEART, NEUROSES OF THE.

—This class includes all those cases in which symptoms of cardiac derangement occur without physical signs of organic disease. Neurotic influences may, and no doubt do, play an important part in structural disease of the heart, but we are now only concerned with uncomplicated neuroses.

The *symptoms* of cardiac neurosis are mainly palpitation, arrhythmia, and alterations in the frequency of the heart's action. It is characteristic of neurotic affections of the heart that they are always more or less paroxysmal in

character. For purposes of convenience the symptoms will be considered separately, but, as a matter of fact, they are commonly combined in varying proportions, one or other symptom predominating.

Palpitation.—Palpitation may be a purely subjective sensation, though it is usually associated with over-action of the heart and signs of vascular excitement.

Some degree of præcordial discomfort or even pain is at times connected with this symptom.

Palpitation may be due to increased reflex excitability of the heart, or to abnormal sensitiveness on the part of the patient to the pulsation of the organ. In the first case, palpitation is the result of impressions transmitted from the digestive, sexual, or respiratory organs, or it may be due to emotional or mental disturbance of various kinds. Flatulent distension and simple dyspepsia are perhaps the commonest causes of reflex palpitation; but, at the same time, it is important to recognize the fact that gastro-intestinal derangement and palpitation may both be the consequence of some disorder of the nervous system. Sexual excesses and masturbation are also frequently concerned in the production of nervous palpitation.

The same symptom again may be induced by such trifling causes as lying on the left side, slight exertion, or the mere entrance of food into the stomach; and palpitation is not uncommonly directly traceable to the influence of tobacco, tea, coffee or alcohol.

When the sense of palpitation is unassociated with any marked objective signs of cardiac derangement, it will often be found that the patients are the subjects of functional nervous affections, such as neurasthenia and hysteria.

Nervous palpitation in some cases is relieved by physical exertion—a point which distinguishes it from the palpitation of organic disease.

Balfour suggests that the relief thus obtained is to be explained by the flushing of the heart's substance with blood as the result of quickened coronary circulation. Persons suffering from anæmia and debility of various kinds are very liable to palpitation, and a similar tendency is at times observed in plethoric conditions. Nervous palpitation is not confined to either sex, though it is undoubtedly more often met with in women than men (*see also* DISEASES OF THE MUSCULAR WALLS OF THE HEART).

Arrhythmia.—All degrees of arrhythmia may occur, including simple intermission, where one or more beats of the heart are dropped at intervals without further disturbance of rhythm, inequality of volume of the individual beats, or a combination of these two conditions, and allorhythmia. In some cases the patient may be unconscious of any cardiac derangement, or, as Balfour says, "an intermission is followed by a thump"—i.e., by a forcible contraction of the ventricle which attracts attention. Some persons are very sensitive to the least cardiac irregularity, and take notice of a simple intermission even when it is not succeeded by a thump. Irregularity of volume is, generally speaking, of more significance than simple intermission, and should always suggest the necessity of repeated examination of the heart under different conditions; but cases are met with in which both forms of arrhythmia are habitually present without any ill-effects, and even without the knowledge of the patient. Arrhythmia, like palpitation, may be a reflex symptom of gastro-intestinal, sexual or emotional origin, and is a common result of the abuse of tea, coffee, tobacco or alcohol. Gout is also believed to be a frequent cause of this condition.

Alterations in the Frequency of the Heart's Action.—The frequency of the heart's action is more often increased than diminished, but changes may occur in either direction as the result of similar causes to those that have been already enumerated. A frequent pulse is often, but not necessarily, associated with a feeling of palpitation.

Tachycardia, a condition characterized by paroxysms of extremely rapid cardiac action, has been referred to under the head of *Palpitation*. This comparatively rare affection, which represents a true neurosis of the heart, may be the result of a transient paralysis of the vagus or of irritation of the accelerator nerves of the heart, and has been attributed to errors in diet, the action of tobacco, alcohol, &c. A similar condition has been observed by Wilks in combination with severe dyspnoea and palpitation in cases of nephritis, mostly of scarlatinal origin, but speedy recovery ensued in nearly every instance.

Uterine displacements and pregnancy have been said to produce a condition of tachycardia in a few instances. Lesions of the cardiac plexus, vagus nerve and medulla oblongata have occasionally

been found in cases where the pulse had been very rapid during life.

A very **infrequent action** of the heart, falling as low as thirty beats in the minute, is sometimes the only sign of any cardiac disorder. In cases of this description the pulse should always be controlled by auscultation of the heart, as some of the beats may fail to reach the periphery in certain degrees of arrhythmia or allorhythmia, and a wrong conclusion may be arrived at concerning the frequency of the heart's contractions. Apoplectiform attacks are occasionally associated with infrequent action of the heart, and are possibly due to cerebral anæmia.

Extreme retardation of the pulse, or the opposite condition of increased frequency, and arrhythmia are sometimes produced by diphtheria, probably from some lesion of the cardiac nerves. Changes in the frequency of the pulse have also been observed in cases of tabes dorsalis.

The term **Irritable Heart** was given by Da Costa to a class of cases occurring among soldiers in which the leading features were palpitation, cardiac pain, dyspnoea on exertion, irregularity of the heart, and a remarkable tendency to increased frequency of the pulse on slight provocation. In these cases a change from the reclining to the upright position alone sufficed to raise the pulse rate to the extent of thirty or forty beats per minute.

This group of symptoms was directly traced in many instances to hard muscular exercise, such as forced marches. In other cases an attack of diarrhoea or fever seemed to be the starting-point of the disorder, the symptoms developing as soon as the soldier returned to his active life.

In the great majority of Da Costa's patients no sign of organic disease existed, but in a small percentage a condition of hypertrophy supervened.

Cases such as these furnish a connecting link between the two groups of functional and organic disease of the heart, and are in all probability connected with cardiac overstrain. A similar train of symptoms occasionally develops as a sequel of acute rheumatism, and is not uncommonly observed in neurotic or delicate persons of both sexes in whom the heart is constitutionally weak.

It may again be stated that one or all of the symptoms that have been considered in detail may be present in a given case.

Angina pectoris is regarded as a neurosis of the heart by some writers, but this topic is treated elsewhere.

Diagnosis.—The diagnosis depends on the presence of characteristic cardiac symptoms without signs of structural disease. The heart sounds are clear, and the first sound is apt to be short and sharp, resembling the normal second sound. Accidental murmurs are occasionally heard, especially when the heart's action is excited, and are almost invariably systolic. Such murmurs may be of cardio-pulmonary origin, or they may be the result of anæmia or relative incompetence of the auriculo-ventricular valves. In all such instances, and where anæmia or persistent arrhythmia exists, careful and repeated examination of the patient in the reclining as well as in the upright position is necessary to enable us to exclude the presence of organic disease. In some cases of anæmia the diagnosis presents great difficulties. Where the frequency of the heart's action is persistently increased, the question of Graves' disease must be taken into consideration, as the development of proptosis and goitre may be preceded for some time by signs of cardiac excitement.

In most cases the neurotic constitution of the patient, the exaggeration of the cardiac symptoms as compared with the physical signs, and the paroxysmal and capricious character of the attacks will point to a correct conclusion.

Prognosis.—The prognosis is favourable as regards the duration of life, but the chances of recovery or improvement depend largely on the nature of the neurosis in individual cases. Where the origin of this affection is most obscure, as in habitual arrhythmia, the prospects of improvement are not very hopeful.

Pathology.—In attempting to account for the occurrence of cardiac neuroses it is necessary to distinguish as far as possible those that are reflex from those that are direct.

The derangement of the nervous mechanism of the heart may be the result of some cause acting on the vagus or accelerator nerves, or on corresponding nerve cells in the medulla oblongata, or in the heart itself. A preponderance of the inhibitory or accelerating centres, or paresis of one or other centre, would account for changes in the rhythm and frequency of the heart's beats, but we know little of the exact mutual relations of these antagonistic influences in the human heart. The intrinsic cardiac

ganglia are believed to be concerned in the co-ordination of the heart's muscular contractions, and it is reasonable to suppose that lesions of these structures may give rise to arrhythmia.

The subjective sensation of palpitation must be conveyed by afferent fibres of the vagus and sympathetic nerves, but the conditions of the heart that originate this sensation are unknown.

It is still a matter of dispute whether neuroses of the heart can lead to organic lesions. This sequence of events may undoubtedly occur in Graves' disease, which is to some extent a cardiac neurosis, but with this exception such a transition is altogether exceptional. It has been suggested that one reason for this difference is to be found in the fact that in the ordinary forms of cardiac neuroses the functional disturbance is essentially paroxysmal, the heart having time to recover in the intervals separating the individual attacks; whereas in Graves' disease the over-action of the heart is continuous, and is therefore more liable to lead to debility and dilatation. In Da Costa's cases of "irritable heart" in which hypertrophy developed, it must be remembered that both conditions were directly connected with muscular exertion, and the irritable stage may have been an indication of commencing dilatation which was followed by compensatory hypertrophy. Sudden death is said to have occurred in cases of neurotic affections of the heart in consequence of fatal inhibition of the organ from shock. It is, however, doubtful whether the heart was altogether free from structural disease in these cases.

Treatment.—In the treatment of cardiac neuroses the general condition and constitution of the patient require careful consideration. Undue emotional excitement, mental overwork, worry or anxiety must be obviated as far as circumstances admit. Moral treatment is of great importance. The patient must be encouraged to believe that the heart is not actually diseased, and too much attention should not be directed to this organ by the physician. Anæmia, debility, neurasthenia, hysteria or gout must be met by appropriate methods of treatment. In such cases a judicious exhibition of iron, strychnine, arsenic, quinine, valerian, iodide of potassium, will often give good results. Plethoric conditions may be relieved by moderate saline purging.

If we have to do with nervous irritability, whether general or cardiac,

bromide of ammonium and the application of a belladonna plaster to the præcordia may be of much service.

When irregularity of the heart's action is a permanent feature, the internal administration of belladonna or atropine may be prescribed. In all cases of reflex origin the cause should, if possible, be removed, but it must be admitted that the determination of the cause is not always an easy matter. The relief of dyspepsia and of morbid conditions of the uterus is sometimes effectual in removing the symptoms of cardiac derangement. The investigation of the question of sexual excesses is a matter requiring great delicacy and tact, but in the case of young men suffering from neurotic disturbance of the heart, which is not explicable on other grounds, this possibility should always be kept in mind and judicious inquiries should be instituted. Patients must be cautioned against the excessive use of tobacco, tea, coffee and alcohol.

Cases of habitual arrhythmia, or where the pulse is very infrequent, often resist all treatment, but fortunately the general health may be in no way affected.

There is much difference of opinion as to the efficacy of digitalis. In uncomplicated neuroses of the heart digitalis is not generally of much use, but in cases of "irritable heart" depending on overstrain, or when the cardiac action is very feeble and rapid, this drug may be prescribed with great advantage. For the relief of the paroxysm, rest, the administration of ammonia, ether or brandy, smelling salts, and the application of an ice-bag to the præcordial region are to be recommended, and in exceptionally severe cases a hypodermic injection of morphia may be resorted to when other measures fail.

PERCY KIDD.

HEART, ACUTE DISEASE OF THE VALVES (Acute Endocarditis).—Inflammation of the endocardium may be either *acute* or *chronic*, the latter being often the sequel of the former. In the great majority of cases the affection of the endocardium is limited to the valves of the heart or occurs in their immediate neighbourhood.

Acute endocarditis may be divided, for practical purposes, into two main groups, *simple* and *malignant*. Although at times it is difficult, or even impossible, to distinguish the two varieties clinically, it will be convenient to discuss them separately as regards their symptoms and

course. The diagnosis is further complicated by the fact that transitional forms are not uncommon, and cases of simple endocarditis may subsequently assume a malignant type.

Simple Endocarditis.—*Symptoms and Course.*—Acute endocarditis in its early stages gives rise to no characteristic cardiac symptoms. The fever which is always present in some degree is to be attributed mainly, if not solely, to the rheumatic or other process on which the endocarditis has supervened. At the same time there is no doubt that endocarditis is in itself an efficient cause of pyrexia, and in certain circumstances exacerbations of fever may, with some probability, be attributed to the endocardial inflammation—*e.g.*, when the rise of temperature coincides with an aggravation of general symptoms that cannot be accounted for by a fresh outburst of rheumatism.

Such symptoms as a rapid pulse and excited action of the heart have been ascribed to endocarditis, but it is more probable that they are simply the effects of pyrexia. Physical examination of the heart is the only means that enables us to detect the presence of endocarditis. The appearance of a systolic murmur, or a prolonged first sound at the apex, is commonly the earliest and only indication that the endocardium is affected, the mitral valve being more prone to the disease than the aortic. Diastolic and præsystolic murmurs may occasionally be detected, and are certain signs of valvular disease; but they are much less common than systolic murmurs in the early stages. It is at times impossible to say whether a systolic murmur is due to structural changes in the valves, to relative incompetence, or to anæmia.

Enlargement of the heart as a consequence of valvular defects requires time for its development, and is rarely met with at this period. Acute dilatation may, however, ensue at a comparatively early date as a result of inflammatory or other affections of the myocardium. When the endocardial lesions are progressive, the functions of the valves sooner or later become impaired, and mechanical disturbance of the intra-cardiac circulation is necessarily followed by some degree of dilatation of the various chambers. The lesions of the valves and their effects are considered under the head of CHRONIC ENDOCARDITIS (*q.v.*). Pericarditis or myocarditis may arise as complications, or they may occasionally precede endocarditis. In other cases

they seem to develop simultaneously. Embolic manifestations are rare accidents of the initial stages of simple endocarditis. Repair is possible when the process has not advanced too far; but in the majority of cases the acute stage is succeeded by contractile fibrous changes, and the patient is left with the signs of chronic valvular disease.

Malignant endocarditis is also known as *ulcerative, diphtheritic, infectious, and septic endocarditis*, but the term "malignant" is adopted provisionally as the least objectionable, a clinical classification only being feasible in the present state of our knowledge.

Symptoms and Course.—The onset of malignant endocarditis may be marked by rigors, headache, vomiting, a sudden rise of temperature and other signs of acute constitutional disturbance, or, occasionally, the disease may develop insidiously. In either case the condition of the heart is apt to be overshadowed by the general symptoms, and except in cases where endocarditis supervenes on old valvular disease or appears in the course of rheumatic fever, where the heart is, as a matter of routine, examined frequently, the affection may escape notice.

Profound prostration is always an early and important symptom. Fever is usually high, and may present an irregular, remittent or even intermittent type, comparable to that of ague. Very severe cases, on the other hand, may sometimes be attended with a comparatively slight elevation of temperature.

Cardiac symptoms are usually late in appearing; but dyspnoea, palpitation, pain and marked physical signs of valvular disease may occasionally develop with great rapidity. The information derived from physical examination, however, is apt to be very equivocal, especially in the case of faint systolic murmurs. When a murmur suddenly appears, or alters in character under observation in a febrile case of doubtful nature, the possibility of ulcerative rupture or laceration of valves should always be carefully considered.

The occurrence of such symptoms as coma, delirium, convulsions, hemiplegia, pain in the region of the spleen, hæmaturia, purpuric skin eruptions, and retinal hæmorrhages, pointing to multiple embolic infarctions, would furnish very strong evidence in favour of the existence of malignant endocarditis. The development of abscesses in different parts of the body, either with or without hæmorrhages, would point in the same direction.

Enlargement of the spleen is almost a constant feature, independently of embolism; and profuse sweats are very frequent. Diarrhœa, meteorism, slight jaundice, albuminuria, pneumonia and pleurisy are also not uncommon complications. Secondary inflammation of the joints is said to occur in some cases without suppuration.

Malignant endocarditis commonly manifests a more or less typhoid or else a pyæmic character.

The resemblance to typhoid fever is sometimes very close, the state of the abdomen, marked with a suspicious skin eruption, the gastro-intestinal symptoms, enlargement of the spleen, the characteristic temperature chart and the general condition all combining to mislead. The pyæmic type, with its repeated rigors, perspirations, hectic irregular temperature and slight icterus, is less common than the preceding. Most cases fall into one of these two categories, though pyæmic and typhoid features are very apt to be associated in varying degrees, and no strict classification is possible. A further division of cases into cerebral, cardiac and other groups, according to the predominant symptoms, serves no practical purpose. Fallacies inevitably arise in attempting to decide whether recovery is possible, owing to the difficulty of distinguishing milder forms of the malignant affection from severe cases of simple endocarditis. A fatal issue ensues in all, or nearly all, well-marked examples of the disease, and is not unfrequently preceded by coma or other cerebral symptoms. Life is rarely prolonged beyond a few weeks, and cases have been known to terminate within a few days.

Diagnosis.—The diagnosis of endocarditis must be based on the results of physical examination of the heart. The malignant form is distinguished mainly by the gravity of the general condition, and by the presence of typhoid or pyæmic symptoms. The generally higher range of temperature, and the marked tendency to splenic enlargement and multiple embolism, are also important characteristics of this variety. The diagnosis of malignant endocarditis from typhoid fever, pyæmia, meningitis and acute disseminated tuberculosis may at times be extremely difficult; but the condition of the heart, the occurrence of cutaneous and other hæmorrhages and the development of acute nephritis are the chief points that would serve to indicate endocarditis. The course of the fever and ætiological considerations may in a minor

degree assist us in arriving at a correct diagnosis.

Prognosis.—In simple endocarditis the prognosis is favourable as regards the immediate present, but the great probability of chronic valvular disease becoming established makes the patient's future very uncertain. In the case of the malignant form the prospect is all but hopeless.

Pathology.—Any part of the endocardium may be invaded, but the valves are nearly always the parts affected, owing to the greater strain to which they are subjected. In adult life endocarditis is almost confined to the left side of the heart, in consequence of the greater variations of pressure to which this side is exposed; whereas, in the fœtus, the right heart, for similar reasons, is alone affected. Affections of the right heart in adults are nearly always secondary to similar disease of the left side. The mitral valve is rather more liable to become affected than the aortic.

The presence of endocarditis in the early stages is shown by the appearance of small transparent nodular projections of the endocardium, which subsequently become invested with a varying degree of fibrinous deposit from the blood. The development of these granulations, or *vegetations*, as they are called, is the result of a small-celled infiltration in the sub-endothelial connective tissue of the valves, which gives rise to small elevations of the endothelial membrane. The inflamed condition of the endocardium occasions a localized thrombosis, in consequence of which the granulations increase in size, and acquire a greyish colour and a more or less granular or uneven surface. In some instances the cellular growth shows a marked disposition to necrosis or ulceration, so that the main change appears to consist in a loss of substance. In malignant or ulcerative endocarditis various kinds of micrococci are always found in the floor of the ulcers, extending to a varying distance into the subjacent tissues. Micro-organisms may also be frequently detected in the superficial fibrinous layers of the vegetations, sometimes in masses. Cases in which they are found in large numbers generally present affinities with the ulcerative form, and belong to the malignant type of endocarditis. Vegetations may vary in size from a pin's head to a bean or a small cherry, the largest growths being generally composed of aggregations of smaller ones. In most cases they are sessile, but they may be

pedunculated, and swing freely to and fro in the blood.

The lesions, whether warty or ulcerative, may be developed on healthy valves or on valves that are the seat of old disease, evidence of old valvular lesions being often found post-mortem in cases of the malignant type, and in those apparently acute in character.

Cases of simple chronic endocarditis may acquire a malignant type independently of the co-existence of any febrile disease, the injured valves apparently affording a favourable nidus for the development of the pathogenic microbes.

The seat of valvular vegetations is determined by the lines of contact of the individual segments of the valve, or rather by the point of maximum pressure. This corresponds, not with the edge, but with a line more or less parallel to, but slightly removed from, the free margin. The auricular surface of the mitral and tricuspid, and the ventricular aspect of the semilunar valves, are the parts that are mainly or exclusively affected. The chordæ tendineæ of the mitral valve, and the posterior wall of the left auricle, are also not unfrequently studded with granulations, those on the latter site often marking the course of the regurgitant stream. In the early stages of their development, the vegetations may be completely absorbed, without any permanent alteration of the valve taking place, or they may gradually disappear, and be transformed by a process of cicatrization into dense fibrous tissue. The results of this process are considered under the head of HEART, CHRONIC DISEASE OF THE VALVES (*q.v.*).

The vegetations may themselves also undergo ulcerative changes, leading to perforation or aneurysm of the valves, or in certain cases to acute aneurysm of the substance of the heart, or of the root of the aorta. Similar accidents may arise in the course of the typically ulcerative form. Rupture of the chordæ tendineæ, or of the curtains, may also occur, and give rise to various valvular defects. Ulceration is often mechanically excited by the friction of pendulous vegetations against neighbouring parts, and in some cases partial aneurysm of the heart's wall is thus produced. The size and position of the vegetations may prevent the adequate closure of the valves, and at times may cause obstruction of the orifices.

Detachment of fragments of the granulations, or of portions of the valves, is not uncommon, and gives rise to embolism and hæmorrhagic infarction in the brain,

spleen, kidney, myocardium, retina, or other parts. Pyæmic abscesses, and purulent meningitis, may also develop in the same manner in malignant forms of endocarditis, from the entrance into the blood of pathogenic microbes derived from the diseased endocardium. Multiple hæmorrhages may occur in both forms of endocarditis, but they are far less common in the simple variety. In some cases, especially of the severe type, embolism is succeeded by inflammatory softening of the coats of the arteries of the brain, mesentery, or extremities, leading to the production of embolic aneurysms.

Endocarditis is sometimes regarded as a primary affection; but in such cases, a careful inquiry will not unfrequently discover evidence of previous ill-defined rheumatic manifestations, chorea, nephritis, or some of the less common antecedents of the disease.

Ætiology.—Simple endocarditis, in the great majority of cases, is the result of rheumatic fever, and only occasionally occurs in connection with other specific diseases, such as scarlatina, diphtheria, measles, typhoid fever, puerperal fever and other septic conditions, pneumonia, gonorrhœa, and syphilis.

Malignant endocarditis may arise in connection with acute rheumatism, scarlatina, diphtheria, pneumonia, and other specific fevers; but more frequently, no such relation can be established. Rheumatic endocarditis is more common in women than in men, and shows a special tendency to attack young persons.

Nephritis and chorea are not uncommon antecedents of endocarditis, and certain ulcerative diseases, more particularly phthisis pulmonalis, seem to be associated with the development of similar lesions of the valves.

Treatment.—The treatment of simple endocarditis practically merges in that of acute rheumatism; but, unfortunately, remedies like the salicylates, which have such a beneficial action on the rheumatic process, seem to have no effect in preventing the development of endocardial complications. The value of complete and prolonged rest in bed, on the other hand, is unquestionable. In cases of malignant endocarditis, we can only adopt measures suitable for other septic conditions—a nutritious diet and stimulants being of the most importance. Drugs like quinine, arsenic and sulphocarbolate of sodium have been tried without much result. Cardiac symptoms depending on the secondary effects of

valvular lesions must be dealt with on the principles set forth in the following article.

PERCY KIDD.

HEART, CHRONIC DISEASE OF THE VALVES (Chronic Endocarditis).—The subject of chronic valvular disease does not readily lend itself to the method of arrangement adopted throughout this work, and in this article a discussion of the general pathology of chronic endocarditis precedes the description of the lesions of the valves, which are treated in the following order:—

- I. Aortic Incompetence.
- II. Aortic Stenosis.
- III. Mitral Incompetence.
- IV. Mitral Stenosis.
- V. Pulmonary Incompetence.
- VI. Pulmonary Stenosis.
- VII. Tricuspid Incompetence.
- VIII. Tricuspid Stenosis.
- IX. Combined Valvular Disease.

Each of these subjects is discussed under the following headings:—

- a. *Pathology.*
- b. *Effects upon the Heart and Circulation.*
- c. *Symptoms and Course.*
- d. *Complications.*
- e. *Physical Examination of the Heart.*
- f. *Pulse.*
- g. *Diagnosis.*

Finally, the PROGNOSIS and TREATMENT of valvular disease is discussed.

General Pathology of Chronic Endocarditis.—This condition consists in a fibrous or cirrhotic thickening of the valves which is commonly associated with contraction, and in many cases with calcification. The diffuse thickening of the endocardium resulting from increased intra-cardiac pressure frequently seen in cases of dilatation and hypertrophy has no clinical significance, and need not now be considered.

A fibrous change in the valves is a sequel of acute rheumatic endocarditis in a large number of instances, but similar lesions may develop insidiously as the results of chronic renal disease, arterio-sclerosis, gout, chronic alcoholism, cardiac overstrain, senile degeneration and syphilis.

In many, perhaps in all, of these conditions the valvular thickening is an effect of increased blood pressure. The close relationship of gout to cirrhosis of the kidney and arterial degeneration probably explains the important part played by this disease in the production of chronic valvular lesions. The in-

fluence of syphilis may also be due to its tendency to induce arteritis.

Heart disease is sometimes said to be hereditary, but it is doubtful whether the apparent transmission of the disease is not due to a tendency to rheumatism, which is generally admitted to be hereditary.

The valves of the left side of the heart are, as a rule, alone affected; the tricuspid and pulmonary valves being rarely involved, except in a secondary manner, or as the result of congenital malformation or fetal endocarditis.

Chronic lesions of the mitral valves are almost always of rheumatic origin, whereas the aortic valves are very prone to degenerative cirrhotic processes, extending from the root of the aorta (atheroma, arterio-sclerosis). The fibrous thickening leads to puckering and distortion of the valves, to morbid adhesions of the individual segments or to shortening of the chordæ tendinæ, whereby the efficiency of the valves is more or less impaired. A growth of vegetations is very liable to supervene on old fibrous induration of the valves, especially where rheumatic attacks recur from time to time. Small hernial protrusions or aneurysms are occasionally developed in the valves, and rupture of these sacs may give rise to incompetence of the valve.

Fibrinous deposits may form on the surface of the valves or in the dilated chambers. When complete closure of the valves is in any way prevented, some of the blood regurgitates or escapes backwards against the current of the circulation, and we then speak of incompetence or insufficiency of the valve. If the lesion cause interference with the passage of blood through the ostium, the condition is described as stenosis, obstruction, or constriction. The two conditions are generally combined in varying proportions. Incompetence without obstruction is not uncommon, depending on contraction or ulceration of the margins of the valves, but stenosis is nearly always associated with some degree of insufficiency.

DISEASE OF THE AORTIC VALVES.—

1. Aortic Incompetence.—*Pathology.*—The morbid change usually consists in retraction of the edges of the rigid and thickened valves. A growth of vegetations, dilatation of the aorta, adhesions of the valves to the aortic wall, laceration, rupture or perforation of the valves, are less common causes of incompetence. It is not unusual to find at the same time slight degrees of narrowing of the

orifice, depending on puckering or partial adhesion of the individual cusps or on the presence of vegetations.

As the result of these changes the valves do not meet accurately during diastole, and no longer fulfil their function of shutting off the blood contained in the aorta from the left ventricle. Some of the blood consequently leaks backwards through the narrow opening between the valves into the wide space of the ventricle, and meets the stream pouring in from the auricle. The eddies that are thus produced give rise to a "fluid vein," as it is called, and the oscillations of the particles of blood are attended with a blowing sound or murmur. The murmur is heard during the diastole, and the closure of the valves being interfered with, the second sound of the heart over the aorta is effaced or modified.

Effects upon the Heart and Circulation.

(1) The left ventricle, now receiving blood from two sources—viz., from the aorta as well as from the auricle, is overfilled, and its cavity becomes expanded. The dilatation of the ventricle is favoured by the fact that distension of its cavity occurs during diastole, when relaxation of its muscular walls is proceeding. Serious embarrassment of the circulation would ensue if this condition were long maintained, but inasmuch as a larger amount of blood has now to be propelled at each systole, the work of the ventricle is increased, and hypertrophy of its walls is developed. These results, as a rule, succeed one another so closely, except in the case of rupture of the valves from traumatic or other causes, that no sudden disturbance of the circulation is induced.

The object of this hypertrophy is to counterbalance the mechanical impediment to the circulation entailed by the valvular defect, and to maintain a mean pressure in the aortic system approaching the normal. In order to do this a larger amount of blood than usual must be pumped into the arteries, so as to allow for the backward leakage of a certain amount into the left ventricle. If the degree of hypertrophy be sufficient this result is secured. The systolic expansion of the arteries is consequently increased, and the pulse acquires certain characters which will be subsequently considered. The dilatation of the left ventricle and the increased intra-cardiac pressure soon react backwards on the left auricle, pulmonary circulation and right heart, and a less degree of dilatation and hyper-

trophy is induced in these chambers also. The relative proportions of dilatation and hypertrophy determine whether compensation is complete or incomplete.

Perfect compensation is at times effected, but in most cases compensation falls short of this standard, though sufficient as long as no excessive demands are made on the heart. The conditions necessary for the development and maintenance of compensatory hypertrophy mentioned in the section on myocardial disease apply here also—viz., a sufficient supply of healthy blood to the muscular tissue of the heart, and an adequate degree of general nutrition.

(2) The effects of aortic regurgitation on the circulation are displayed in the first instance by insufficient filling of the arteries, and in a less degree by the engorgement of the lungs and veins of the systemic and portal circulation. In proportion as hypertrophy is developed the tendency to arterial anæmia is diminished, and when compensation is complete no ill effects whatever may be noticeable. The strain to which the arterial walls are subjected by the contraction of the hypertrophied ventricle leads to atheromatous changes in the intima, and the loss of elasticity which results, adds to the already increased work of the ventricle. This condition of arterio-sclerosis may attain to extraordinary dimensions when hypertrophy of the left ventricle occurs, even in young persons in whom a primary arterial degeneration can be excluded.

The duration of compensation is liable to great variations, depending not merely on the state of the coronary circulation and the general quality of the blood, but also on the power of resistance possessed by the neuro-muscular tissues of the heart in different individuals, on the nature of the mechanical defect of the valves, and on the age of the patient.

When valvular disease is progressive, and in the case of young, growing persons, compensation is less likely to be long maintained. Rupture of the valves, whether traumatic or spontaneous, is naturally unfavourable to the development of compensation, as, from the suddenness with which the lesion arises, the heart has not time to accommodate itself to the altered conditions of the circulation. The slight and transient effects of experimental laceration of the valves in animals do not invalidate the truth of the above statement in the case of the human heart. It is doubtful whether traumatic rupture ever occurs

without some previous alteration in the structure of the valves. Under the most favourable conditions a time comes in all serious valvular disease when the cardiac muscle becomes exhausted from the effects of distension and overwork, and compensation reaches its limits. Increasing distension of the left ventricle not infrequently brings with it dilatation and relative incompetence of the mitral valve, which may temporarily relieve the ventricle and afford time for a brief rally on the part of the heart. The transition from the stage of compensation is shown by progressive dilatation and insufficiency of the heart, visceral stasis, cyanosis, and dropsy; in other words, by the same results that follow dilatation of the heart from primary affections of the myocardium. The muscular element is thus seen to be the determining factor, as far as compensation is concerned, in all cardiac disease, whether myocardial or valvular.

Rupture of Compensation has hitherto been considered as a very gradual process, except in the somewhat rare cases of traumatic rupture of the valves, but the same result is not uncommonly precipitated more or less acutely as the result of myocardial degeneration from any cause—over-strain, relapses of rheumatism, or acute intercurrent disease of any kind, especially pneumonia and bronchitis, effusions into serous cavities, uterine disorders (particularly pregnancy and the development of the menopause), digestive disturbances, mental anxiety, worry or overwork, and the abuse of alcohol and tobacco.

Symptoms and Course.—The symptoms of aortic incompetence, as of all valvular affections, depend on the existence and degree of compensation—that is to say, on the extent to which the mechanical defect of the valves and its consequent dilatation are counterbalanced by hypertrophy. In some cases the hypertrophy is so extensive that the effects of the valvular lesion are completely masked. The mean pressure in the aortic system does not fall appreciably below the normal, and no backward congestion ensues.

Under these circumstances great physical exertion may be undergone without difficulty. But it is the exception for compensation to be so perfect, and it usually happens in what would be regarded as well compensated cases that some dyspnoea is experienced when the work required of the heart exceeds a certain moderate standard.

Dyspnoea is less common in aortic than mitral disease, owing to the fact that pulmonary engorgement is less pronounced in the former affection. In most cases a tendency to anæmia is observed in the subjects of aortic incompetence, even when compensation is fairly satisfactory. Throbbing and noises in the head, giddiness, faintness, and flashes of light, depending upon the altered condition of the cerebral circulation, are also frequently complained of. When dilatation preponderates over hypertrophy the symptoms common to cardiac failure or insufficiency appear, dyspnoea, palpitation, a sense of depression, pain in the præcordia, together with signs of venous stasis, œdema of the lungs, and general dropsy. The signs of backward congestion develop earlier and are more marked in mitral disease, and will be further considered under that head.

The stage of failing compensation may be marked by various degrees of cardiac arrhythmia and by acceleration of the pulse, but, as before stated, there is no constant relation between arrhythmia and failure of the heart's contractile power; and disturbance of the heart's rhythm is seldom pronounced in aortic disease.

Complications.—Pericarditis, angina pectoris, cardiac asthma, embolism, thrombosis of the heart, hydrothorax, ascites, and general dropsy may complicate cases of aortic incompetence. Large effusions into the pericardium, pleura, or peritoneal cavity are very grave complications, owing to their interference with the heart's action and with the movements of the diaphragm.

Enlargement of the left ventricle at times is sufficient to cause collapse of the lower lobe of the left lung, owing to the pressure which it exerts, and thus increases the dyspnoea by curtailing the respiratory surface of the lung. The œdematous skin of the scrotum and lower extremities is very liable to erysipelas and other forms of spreading inflammation. Death commonly ensues with œdema of the lungs, general dropsy, and asthenia, but a sudden termination may occur, and is more often observed in aortic incompetence than in any other valvular affection. This may be due to anæmia of the brain or to diastolic arrest of the heart from over-distension of the ventricle. In exceptional cases sudden death may be the result of embolism of the coronary artery, or of cerebral hæmorrhage, depending on rupture of a

small aneurysm or some atheromatous branch of an intra-cranial artery. Gangrene of the extremities is an occasional consequence of embolism. Mental derangement of the melancholic type sometimes develops.

Physical Examination of the Heart.

— *Inspection* shows displacement of the apex beat outwards and downwards, with diffused pulsation and bulging of the præcordia.

Palpation detects forcible, heaving impulse over the left ventricle, and occasionally a diastolic thrill at the base of the heart, or over the lower end of the sternum. When the amount of regurgitation is extreme, and compensation has failed, there may be a diastolic impulse at the apex.

Percussion.—The cardiac dulness is increased outwards and downwards, but not in other directions as a rule. The dulness may, however, when the right ventricle has undergone secondary enlargement, extend further to the right than the normal line, which corresponds with the left edge of the sternum, or when the increased size of the left heart has led to displacement of the right ventricle, towards the corresponding side.

Auscultation.—At the base of the heart and down the sternum a diastolic murmur is heard, wholly or partially replacing the second sound of the heart. This murmur, which is usually blowing and high pitched in character, and may at times be musical, is often heard all over the sternum, and even at the apex of the heart. The area of maximum intensity usually corresponds with the left margin of the sternum between the third and fifth ribs, or with the mid-sternum. The murmur is frequently inaudible above the third rib, and at times it is louder at the ensiform cartilage than elsewhere. The fact that the diastolic murmur is heard with greater loudness below and to the left of the aortic valves is to be explained partly by the conducting qualities of the sternum, which lies immediately over the valves, and also by the propagation of the murmur in the axis of the blood-stream regurgitating into the left ventricle from the aorta. The presence of a second sound with the diastolic murmur shows that the valves are capable of some degree of closure, and consequently that incompetence is not very extensive. Balfour believes that when the murmur is well conveyed down the sternum, and is heard at the apex, the valves are rigid and permit of a free reflux towards the

apex of the ventricle, whereas a limitation of the murmur to the immediate anatomical site of the aortic orifice indicates a more vibratile condition of the valves, attended with obstruction of the outlet.

The first sound over the aorta remains clear in uncomplicated cases of incompetence. But when, as often happens, some degree of narrowing of the orifice co-exists, or when the aorta is dilated without alteration in the capacity of the opening, the conditions for the production of a fluid vein are present, and a systolic murmur partially or wholly replaces the first sound over the aortic valves. A systolic murmur in this region may also be the result of anæmia. The diagnosis of systolic basic murmurs will receive further attention in the next section, on Aortic Stenosis. In many cases a double aortic murmur is audible.

The heart sounds at the apex may be perfectly normal, or the diastolic murmur may be heard here also. The first sound is usually clear, but it may be feeble and dull even when the efficiency of the mitral valve is unaffected. Traube explained this in the following manner: The ventricle, receiving blood from the aorta as well as from the auricle, is more rapidly filled, and the mitral curtains are floated up and come into contact before the diastole is complete; consequently, the ventricular contraction does not cause a sufficiently sudden tension of the valves to give rise to audible vibrations as usual, and the valvular element of the first sound is lost or modified. A systolic murmur at the apex may be due to actual mitral disease, or to relative incompetence of the valve from dilatation of the left ventricle.

Auscultation of large arteries, such as the carotid and femoral, sometimes reveals a double murmur (Duroziez), the result of compression of the vessel by the stethoscope, which gives rise to a fluid vein not only during the onward passage of blood past the point of constriction, but also during the diastolic reflux towards the ventricle. In other cases a diastolic murmur alone can be heard in the large arteries. A diastolic or a double murmur in the arteries is a proof that the aortic valves are highly incompetent.

The first sound in the carotid artery is often replaced by a systolic murmur when no appreciable narrowing of the aortic orifice exists and when no systolic murmur is audible in the aortic area. The murmur is believed to be due to

forceful stretching of the arterial wall by the powerful systole of the ventricle. When the valves are seriously incompetent the second sound can no longer be heard in the carotids. Traube's "double sound" in the femoral artery is no longer considered to be characteristic of aortic regurgitation, and doubts exist as to the interpretation of this sign. Some believe that it only occurs when tricuspid incompetence is also present, the first element of the sound being due to sudden tension of the valves of the femoral vein caused by the systole of the right ventricle or auricle, the second division being caused by the forcible expansion of the artery.

Pulse.—The pulse of aortic incompetence is characteristic, and has received many different names—Corrigan's pulse, water-hammer pulse, collapsing, jerking, quick or sudden pulse. Owing to the hypertrophy and dilatation of the ventricle, the volume of the pulse is large, the forcible and sudden expansion of the artery being followed by a rapid subsidence of the wave, corresponding to the diastolic emptying of the artery in two directions—viz., onwards into the capillaries, and backwards into the ventricle. The initial pressure is high, but the mean pressure in the arteries is low, which accounts for the tendency to anæmia observed in this disease. The peculiarities of the radial pulse are generally intensified by raising the arm. Sphygmograms show steep lines of ascent and descent, the apex of the tracing being very pointed.

The pulse is usually somewhat more frequent than in health, but is generally free from any form of irregularity, except in the terminal stages. The peripheral arteries are often thickened, dilated and tortuous, and their pulsations are clearly visible owing to the hypertrophy of the ventricle.

In some cases a capillary pulse may be discovered in the skin, nails, mucous membranes or retina. If the skin be gently rubbed, the flush which is produced can be seen to become slightly paler with each diastole. A systolic pulse may also occasionally be visible in the veins on the back of the hand or in other parts.

Capillary and venous pulsation are due to the fact that in consequence of the hypertrophy of the left ventricle, combined with dilatation of the small arteries, the pulse-wave is transmitted into the capillaries, or even into the veins. Neither of these conditions is patho-

gnomonic of regurgitation through the aortic valves.

The *diagnosis* of aortic incompetence usually presents little difficulty, and depends primarily on the presence of a diastolic aortic murmur, associated with signs of hypertrophy and dilatation of the left ventricle, and with the characteristic collapsing pulse. A diastolic murmur has been absent in certain cases where the aortic valves have been found after death to be distinctly incompetent. Careful and repeated examination of patients in various positions—sitting, standing, and lying down—will, however, often prevent us from failing to detect a murmur in aortic regurgitation as in other valvular diseases. The extent of the incompetence of the valves is not to be gauged by the loudness of the murmur, but the presence of a diastolic murmur in the arteries, the absence of the second sound over the aorta and carotid artery, pronounced dilatation and hypertrophy of the left ventricle, and a jerking pulse, coupled with marked anæmia and subjective cardiac symptoms, would collectively show the lesion to be a severe one.

Nature of the Lesion.—In attempting to decide whether the valvular disease is primarily due to endocarditis or to arterial degeneration, considerations of age, sex and previous diseases, as well as the condition of the patient, have to be taken into account. In young persons, especially females, and in those with a clear history of acute rheumatism, the affection is almost certainly endocarditis. In older people, more particularly in the case of men, a history of hard muscular work, gout, chronic renal disease, syphilis or alcoholic excess would point to arterio-sclerosis in the absence of rheumatic antecedents. Degenerative conditions of the peripheral arteries also possess much diagnostic importance; but it must be remembered that these changes may themselves be secondary effects of hypertrophy of the left ventricle. In cases of this description occurring in elderly patients who have had undoubted attacks of rheumatic fever it may be very difficult to decide this point.

II. Aortic Stenosis.—*Pathology.*—Aortic stenosis commonly depends on thickening, puckering and calcification of the valves or adhesion of the individual cusps, which may be the result of endocarditis or atheromatous disease of the aorta. Vegetations may also assist in producing stenosis. This

lesion is more likely to occur in elderly people.

Conditions that interfere with the passage of blood from the ventricle into the aorta also, as a rule, prevent the valves from fitting closely together during diastole. Consequently, stenosis is generally combined with a certain amount of incompetence. We are now concerned only with the comparatively rare cases in which stenosis exists alone, or distinctly preponderates over incompetence.

Effects upon the Heart and Circulation.

—When the ventricle contracts, blood is forced through the constricted opening into the wide aorta beyond, and, the conditions for the production of a fluid vein being present, a systolic murmur replaces the first sound. Owing to the rigidity of the valves preventing their complete closure, the second sound is weak or is replaced by a diastolic murmur. At times the second sound is quite inaudible where no diastolic murmur is present. The effect of aortic stenosis is to cause hypertrophy of the left ventricle without much dilatation. The intra-ventricular pressure is increased during systole, but not during the period of diastolic relaxation, as in the case of incompetence; hence the slight degree of dilatation that results. When the amount of stenosis is considerable, the arteries receive a smaller quantity of blood at each systole, the volume of the pulse becomes reduced and a condition of anæmia is developed.

In response to the increased resistance to its discharge the ventricle contracts in a slower and more prolonged manner in order to empty its cavity completely. Unless the obstruction be very great, the efficiency of the circulation is not appreciably affected, and the mean pressure in the arteries is fairly well maintained. Backward congestion develops even at a later date than in aortic incompetence, in consequence of the marked preponderance of hypertrophy over dilatation of the ventricle.

Compensation, as a rule, is longer preserved in aortic stenosis than in any other form of valvular disease, if the necessary conditions of cardiac and general nutrition are not wanting. Atheromatous obstruction of the orifices or trunks of the coronary arteries has a most injurious effect on the heart in cases of stenosis as well as of incompetence of the aortic valves, involving, sooner or later, myocardial degeneration and debility. The remarks made in the last

section concerning the duration of compensation and the causes that determine its rupture apply equally to the present affection.

Symptoms and Course.—Symptoms do not appear until the lesion reaches such dimensions that the circulation in the arteries undergoes considerable diminution. A tendency to syncope, giddiness, epileptiform attacks and other symptoms of cerebral disorder, coldness of the extremities and marked anæmia are then developed. Rupture of compensation is indicated by the signs and symptoms already described, and death may occur from the results of cardiac failure. In other instances a sudden termination may ensue from syncope, or from accidents such as apoplexy, cerebral embolism and angina pectoris.

The complications liable to arise in this affection do not differ in any important respect from those that occur in the case of incompetence.

Physical Examination.—Displacement of the apex beat and increased cardiac dullness outwards and downwards, a deliberate, but not very powerful impulse, a systolic thrill and murmur over the aortic valves are the physical signs met with in well-marked instances.

The apex beat at times is weaker than normal, although, as we have seen, hypertrophy of the left ventricle is a necessary result of the valvular lesion. Traube believed this to be due to the fact that the obstruction to the discharge of blood into the aorta hinders the systolic recoil of the heart, which, according to the theory of Gutbrodt and Skoda, is an important factor in the production of the normal apex beat. Others have supposed that the slow, deliberate contraction of the left ventricle accounts for the feebleness of the impulse.

The systolic murmur is usually loud and rasping, and is often, but not necessarily, accompanied by a thrill; it may, however, be soft, and occasionally is musical. The murmur is heard at the base of the heart, and is generally conveyed along the course of the aorta into the carotid arteries. It may also be diffused over the whole præcordia, but, on the other hand, it is sometimes confined to the right border of the sternum at the level of the second or third ribs. Occasionally the murmur may disappear from weakness of the left ventricle. The second sound over the aorta is, in most cases, either weak or replaced by a diastolic murmur. At times it may be quite inaudible.

The *pulse* of well-marked aortic stenosis is infrequent and of small volume, but deliberate and sustained. Arrhythmia is rarely observed. Sphygmographic tracings exhibit a rounded apex and a gradual ascent and descent, depending on the prolonged systole and diastole of the ventricle.

The *diagnosis* of this lesion turns, not merely on the presence of a systolic murmur over the aortic valves, but also on the condition of the left ventricle and on the nature of the pulse. The extent of the obstruction can best be estimated by attention to the last two points.

Dilatation of the arch of the aorta may be mistaken for aortic stenosis, but the detection of the pulsations of the aorta in the episternal notch, with some degree of dulness over the manubrium sterni, the larger volume of the pulse and the fact that the second aortic sound is invariably accentuated unless the valves be incompetent, will enable us to recognize the former affection.

The systolic murmur sometimes heard in sacculated aneurysm of the arch can hardly be attributed to aortic stenosis if the pressure signs of aneurysm be not overlooked. Attention to the character of the pulse and to the state of the left ventricle will generally prevent a wrong interpretation being put on the systolic basic murmur of anæmia.

DISEASE OF THE MITRAL VALVE.—
III. Mitral Incompetence.—*Pathology.*
—Incompetence of the mitral valve—one of the commonest of all valvular lesions—is, in most instances, the result of contraction of the free edges of the curtains or of shortening of the chordæ tendinæ.

Rupture of the chordæ or cusps adhesion of the valves to each other or to the cardiac walls, perforation of the curtains and a growth of vegetations may also produce the same effect. Contractile lesions of the mitral valve may be said to be invariably due to chronic endocarditis. Atheromatous patches are not unfrequently met with, especially in the large anterior flap, but it is doubtful whether atheroma is ever a direct cause of derangement of the mitral valve. Relative incompetence is frequently brought about by dilatation of the left ventricle and relaxation of the papillary muscles and of the muscular fibres surrounding the mitral orifice. The fibrous structure of the valve curtains does not admit of the same degree of distension, and in consequence the flaps no longer fit accurately together.

Effects upon the Heart and Circulation.

—The function of the mitral valve is to shut off the left auricle from the left ventricle during the systole of the latter.

When the efficiency of the valve is unaffected the curtains are gradually floated up during the latter part of diastole, and are brought into contact at the commencement of the ventricular systole. The blood contained in the ventricle is then driven in the direction of least resistance—viz., into the aorta.

Closure of the mitral valves is assisted by simultaneous contraction of the papillary muscles and of the muscular fibres, which partially encircle the mitral orifice, so that the diameter of the opening is greatly reduced during systole. At the same time the systolic shortening of the papillary muscles prevents the flaps from being forced backwards into the auricle by the increased pressure in the ventricle.

The sudden tension to which the mitral valves are subjected by their closure gives rise to audible vibrations which constitute one factor of the first sound of the heart. When the accurate approximation of the mitral segments is interfered with by any of the morbid changes just enumerated, some of the blood which ought to be pumped from the ventricle into the aorta escapes backwards against the current of the circulation into the auricle.

The regurgitant stream flowing through the narrow slit separating the imperfectly closed valves into the wider space of the left auricle comes into collision with the onward current entering from the lungs. A fluid vein is produced, and a murmur is heard during the systole of the ventricle. Owing to the regurgitation of blood from the ventricle, the left auricle at the end of diastole contains the normal volume of blood received from the lungs plus the amount that has leaked backwards from the ventricle. This increase in the contents of the auricle involves dilatation, and, as the mass of blood to be discharged at each auricular systole is augmented, hypertrophy is superadded. As the result of the increased capacity of the auricle a larger quantity of blood than usual is now thrown into the left ventricle during diastole. Dilatation of the ventricle ensues, and, in consequence of the extra work thrown on this chamber by the increase in the volume of blood that has to be propelled at each systole, hypertrophy is also developed.

Simultaneously with these changes in the left heart, dilatation and hypertrophy

of the right ventricle and auricle are induced by the engorgement of these cavities necessitated by the derangement of the mitral valve. The pulmonary artery and veins undergo dilatation, the capillaries become distended and varicose, and a condition known as "brown induration of the lung" results.

From what has been said it will appear that the effects of mitral incompetence can only be compensated by hypertrophy on the part of the right and left ventricles. The walls of the auricles are so thin that hypertrophy in their case plays comparatively an unimportant rôle.

Turning now to the effects of the valvular lesion on the peripheral circulation we can see that so long as the hypertrophy of the two ventricles is sufficient to neutralise the leakage at the mitral orifice, the volume of blood discharged into the aorta at each systole does not appreciably decline and the circulation is therefore not interfered with. The conditions necessary for the development of hypertrophy and the circumstances that determine the duration of compensation have been described in speaking of aortic disease and need not be repeated. This state of things may last for years, but in most cases compensation is less perfect and the volume of blood discharged from the ventricle at each systole, and the pressure in the aortic circulation undergo some diminution. As a necessary result the pulmonary circulation and right heart become overfilled. This backward congestion may remain limited to the lesser circulation and right ventricle for a considerable time, and beyond a tendency to dyspnoea on extra exertion, dependent upon the high tension in the pulmonary vessels, the patient may present no symptoms of circulatory disorder. Sooner or later this stage is passed, and engorgement of the veins of the portal and systemic circulation is established, frequently culminating in dropsical effusions.

This period, which corresponds to the stage of progressive cardiac dilatation and definite failure of compensation, is commonly associated with relative incompetence of the tricuspid valve which has its origin in the increasing distension of the right ventricle. Rupture of compensation may be the direct result of progressive incompetence of the mitral valve, or of debility and dilatation of the right ventricle, in which case it is generally a very gradual process. On the other hand, failure of the heart may be precipitated acutely by the various

causes mentioned in the case of aortic incompetence.

In most cases the valvular disorder and compensatory changes go hand in hand, the development of the former being very gradual.

When incompetence is abruptly induced or when it undergoes a sudden increase in consequence of rupture of some portion of the valvular apparatus, as in certain cases of malignant endocarditis, derangement of the circulation is developed acutely and less time is given for the heart to accommodate itself to the altered conditions under which its work has to be carried on.

Symptoms and Course.—During the stage of compensation there may be no symptom of any kind, and the patient may be quite unaware of the existence of disease. It is more usual, however, to find that slight degrees of dyspnoea are evoked by any unwonted exertion even in compensated cases. This tendency is more marked in mitral than in aortic disease, owing to the inevitable rise of pressure in the pulmonary capillaries entailed by lesions of the former valve. The overfilled condition of the lesser circulation and of the bronchial veins predisposes to bronchitis, and attacks of this kind are very commonly the determining cause of rupture of compensation. The onset of cardiac failure is evidenced by the symptoms of myocardial debility which have so often been described, dyspnoea, palpitation, a sense of oppression, cyanosis and congestion of the viscera.

The subjects of mitral disease often present a dusky-red or bluish colour about the cheeks, lips, nose, ears, and tips of the fingers and toes. Venous stigmata are also frequently present on the face. The conjunctivæ are anæmic, and not infrequently somewhat yellowish, the same icteric tint being observed in the skin. In other cases the complexion has a pale, ashy hue, suggesting imperfect aëration of the blood. Purpuric skin eruptions, mainly involving the lower extremities, may arise during the later stages of the disease.

The presence of fully developed signs of failing compensation does not preclude the possibility of recovery. Patients with great cardiac dilatation, cyanosis, visceral congestion and dropsy may, in a few weeks, be restored to comparative health by timely and suitable treatment. As a rule the danger increases with each successive attack of cardiac failure, and recovery is wont to

become gradually less perfect. The fatal termination is usually reached by a process of slow asphyxia, depending on the progressive dilatation and enfeeblement of the heart, more particularly of the right ventricle. The development of Cheyne-Stokes' respiration is at times the precursor of the end. Sudden death is decidedly uncommon.

The effects of venous stasis are commonly so pronounced in mitral disease that some mention may be made of them again at this point.

Pulmonary.—Dyspnoea, the cardinal symptom of pulmonary engorgement, is often associated with a troublesome cough and a profuse watery secretion. Hæmoptysis may occur as the result of rupture of small vessels or of embolic infarction, secondary to thrombosis of the right heart. Signs of bronchitis or of oedema confined to, or most marked at, the bases of the lungs, and an accentuated pulmonary second sound, are also significant of pulmonary engorgement.

Portal.—Tenderness and enlargement of the liver with persistent dyspepsia, evidenced by irregular action of the bowels (constipation and diarrhoea alternating), nausea, flatulence, and epigastric pain, are sometimes very early signs of disturbed compensation.

Renal.—Quantitative as well as qualitative changes in the urine often furnish most valuable information concerning the vigour of the circulation. A reduction in the amount of urine in a case of cardiac disease, whether accompanied or not by albuminuria, shews that the circulation in the glomeruli is at a low ebb, and that the waste products of metabolism are being excreted in diminished quantity.

In some cases it may be difficult to determine whether albuminuria and dropsy are primarily cardiac or renal. The presence of granular casts and of a large amount of albumen in the urine, together with a waxy, anæmic tint of the skin, point to the kidney as the organ mainly concerned. In certain instances, however, a decision may be impossible. The gradual ascent of the dropsical effusion from the lower extremities to the upper parts of the body, and conversely, the earlier appearance of oedema of the eyelids and face, may help us to a correct conclusion. Unfortunately, the statements of patients as to the order in which different symptoms have occurred, are not always reliable. It should also be remembered that renal and cardiac disease may co-exist. These

difficulties are less likely to occur in the case of mitral than aortic affections, the latter being more frequently associated with cirrhosis of the kidney and arterial degeneration.

Uterine engorgement not uncommonly leads to disorders of menstruation. Sterility is by no means rare.

The complications that are apt to occur in mitral disease do not differ from those to which aortic cases are liable, with the exception of angina pectoris, which seems to be almost unknown. At the same time, the tendency to engorgement of the viscera and to dropsical effusions is far more pronounced in lesions of the mitral valve.

Physical Examination of the Heart.

—**Inspection.**—The apex beat is displaced outwards, and bulging of the præcordia may be observed in young persons with elastic chest walls.

Palpation.—Diffused forcible pulsation is felt, sometimes more marked towards the sternum and in the epigastrium—i.e., over the right ventricle. A systolic thrill is occasionally perceptible at the apex.

Percussion.—The area of cardiac dullness is increased outwards and somewhat upwards at first, and when the enlargement of the right ventricle is considerable, the dullness may extend across to the right border of the sternum, or even further in this direction.

Auscultation.—At the apex a systolic murmur is heard, wholly or partially obscuring the first sound. The second sound in this region may be clear, weak, or inaudible, and when stenosis co-exists, a diastolic or præstolic murmur may be superadded. The heart sounds in the aortic area are unaltered. The pulmonary second sound is accentuated, and at times reduplicated. The systolic murmur is sometimes very loud, and may be heard all over the præcordia. In exceptional cases the point of maximum intensity of the murmur may be situated as high as the third rib or second intercostal space, close to the sternum. The murmur is generally conveyed outwards towards the axilla, and is often heard at the angle of the left scapula. When it is very loud it may be audible over both scapulæ, or even over the whole thorax.

The displacement of the apex beat to the left is partly the result of the hypertrophy and dilatation of the left ventricle, but it is also indirectly due to the enlarged condition of the right ventricle, which by its increased weight causes the heart to assume a more horizontal position, and tilts the apex outwards. When

the degree of regurgitation is considerable, and more especially when the vigour of the left ventricle is preserved, the systolic apex murmur is generally well conveyed to the angle of the left scapula—i.e., in the axis of the blood-stream regurgitating into the left auricle. In those cases where the murmur is heard louder over the position of the mitral valve itself—viz., at the third left costo-sternal articulation—than at the apex, it is probable that the cause is to be found in great dilatation of the left auricle and in retraction of the edge of the left lung, allowing the dilated auricle to approach closer than usual to the front of the chest. In the terminal stages the development of relative incompetence of the tricuspid valve is often revealed by the appearance of an independent systolic murmur over the ensiform cartilage, and by systolic pulsation of the distended jugular veins.

The characteristic murmur may occasionally be absent in cases of mitral incompetence, where great debility of the left ventricle exists.

Pulse.—The pulse shows no abnormality during the stage of compensation, but when failure commences the pulse-wave becomes smaller, the tension is lowered, and various degrees of arrhythmia appear. Inequality of volume of the individual beats is of more serious import than mere intermission, where some beats are dropped at intervals.

Sphygmographic tracings do not show any characteristic features in mitral incompetence.

Diagnosis.—A systolic apex murmur, enlargement of the right ventricle and accentuation of the pulmonary second sound are the characteristic signs of mitral incompetence.

In attempting to estimate the extent of the valvular lesion, more importance is to be attached to the evidence of its secondary effects on the heart and circulation, than to the character of the murmur.

IV. Mitral Stenosis.—*Pathology.*—Obstructive disease of the mitral valve is nearly always a chronic process depending upon fibrous thickening and contraction of the valvular ring, and adhesion of the curtains to one another, whereby the orifice is often reduced to a mere chink or fissure, “the button-hole type”; or again, stenosis may be due to thickening and shortening of the chordæ tendineæ, which draw down the margins of the thickened and adherent valves towards the floor of the ventricle, “the funnel-shaped variety.” Combinations

of the two forms are frequently met with. These changes are the effects of a gradual fibrous thickening, or chronic endocarditis. Luxuriant vegetations may occasionally produce obstruction, but, as a rule, they are not associated with fibrous lesions. Mitral stenosis is specially common in women, and a definite history of rheumatism is often wanting. Some authors regard the lesion as congenital in such cases, but it is, at least, equally probable that the valvular disease represents the remains of slight rheumatic attacks during childhood, which have been forgotten. It has been suggested that the fact that chorea is more common in girls than boys, may help to explain the disproportion between the sexes.

Effects upon the Heart and Circulation.

—The results of stenosis are in the main the same as those of incompetence as far as the peripheral circulation is concerned. The obstruction at the mitral opening leads to backward engorgement of the left auricle, pulmonary circulation and right heart, and to imperfect filling of the left ventricle and aortic system. The left auricle being unable to empty itself completely becomes dilated and hypertrophied, and the degree of enlargement of the right ventricle that is produced is even greater than in the case of incompetence. Similar changes are induced in the pulmonary vessels, and in the lungs in both forms of mitral disease.

The left ventricle, receiving a smaller quantity of blood than usual, has less work to do, and is commonly found in a state of atrophy after death. When the left ventricle is hypertrophied in mitral stenosis, it is probable that incompetence was the initial lesion, or that increased peripheral resistance in the arterial system (renal disease, or arterio-sclerosis), has been in operation. As the lesion of mitral stenosis almost always involves some degree of rigidity, the valves are commonly unable to meet accurately during the ventricular systole, and stenosis is complicated by incompetence. Where obstruction is the predominant condition, however, the term mitral stenosis may be employed. It is obvious that the narrowing of the orifice must hinder the passage of blood from the auricle into the ventricle during the ventricular diastole, and the blood escaping from the auricle has to pass through a narrow opening into the wide ventricle beyond. A fluid vein is consequently produced, and a murmur is

heard during the diastolic period of the cardiac cycle.

Compensation in mitral stenosis depends only to a very slight degree on the amount of hypertrophy of the thin-walled left auricle, but is determined by the condition of the right ventricle on which the stress of the intra-cardiac circulation mainly falls. The pulmonary engorgement is greater in stenosis than in incompetence, and rupture of vessels and profuse hæmoptysis are far more often observed in the former affection. When the mitral constriction is slight, and hypertrophy of the right ventricle is adequately developed, the amount of blood thrown out into the aorta at each systole does not fall much below the average, and the circulation is unaffected. If the lesion be severe the pulse is always smaller than in health.

In cases where stenosis has existed from an early period of life, the aorta and its branches are found to be very narrow and undeveloped. This condition, known as "hypoplasia of the aortic system," increases the mechanical difficulties which the heart has to overcome, and is to be regarded as an unfavourable element.

No special mention is required of the conditions on which the duration of compensation depends, or of the circumstances which lead up to cardiac failure, after what has been said in previous sections. It may be stated, however, that rupture of compensation from pulmonary causes is even more common in stenosis than in incompetence of the mitral valve.

The *symptoms, course, and complications* of mitral disease are the same, whether the affection be obstructive or regurgitant.

Physical Examination of the Heart.

—*Inspection.*—Slight bulging of the præcordia may sometimes be detected, and the apex beat is slightly displaced outwards.

Palpation discovers diffused forcible pulsation over the right ventricle, and a præ systolic thrill is frequently felt at the apex.

Percussion.—The area of cardiac dullness is increased upwards to the right, and in a less degree to the left also.

Auscultation.—At the apex a præ systolic murmur is heard running up to the first sound, which is short and abrupt, resembling the normal second sound. The second sound at the apex may be audible, and is not unfrequently reduplicated at this point, as well as over the

right ventricle and the pulmonary artery. The pulmonary second sound is accentuated. At times the murmur may be prolonged almost throughout the whole diastole, commencing directly after the second sound, and becoming rougher and louder during the latter part of the diastolic period. The early diastolic and the præ systolic portions of this murmur are occasionally separated by a brief interval. In rare cases a murmur may be heard during the commencement of the diastole alone, as in the case of aortic regurgitation. The præ systolic murmur is frequently confined to the immediate neighbourhood of the apex, though at times it may be diffused widely over the præcordia. Except in cases of this description, where the murmur is generally very loud, it is rarely heard at the angle of the left scapula, and, unlike the systolic mitral murmur, it is not conveyed towards the left axilla. The præ systolic murmur is generally low-pitched, rough, and churning, but it is subject to great variations of pitch and quality.

In order to understand the method of production of this murmur it must be remembered that the long pause of the cardiac cycle comprises not merely the active dilatation of the ventricle, but also the short period of auricular contraction which immediately precedes the systole of the ventricle.

The occurrence of the murmur just before the first sound is to be explained by the sudden acceleration of the blood current through the narrowed mitral orifice caused by the contraction of the left auricle, the flow during the earlier portion of the diastole being comparatively noiseless, owing to the low pressure at which the blood pours into the left ventricle. The presence of an early diastolic murmur is probably due partly to the suction action of the actively dilating ventricle, and partly to the high tension existing in the pulmonary circulation.

The loudness of a murmur depends less upon the size of the orifice than upon the rapidity with which the fluid passes through it. Hence the degree of hypertrophy of the left auricle, the pressure in the pulmonary veins, and the activity with which the left ventricle dilates during diastole, are the conditions which mainly determine the existence or loudness of the murmur of mitral stenosis. The second sound at the apex usually disappears when narrowing reaches a certain point; the præsys-

toxic murmur and abrupt short first sound persisting.

Absence of the second sound is explained by Broadbent by the overlapping of the left apex by the enlarged right ventricle, and by the weakening of the aortic second sound consequent upon the low pressure in the systemic arteries. In the later stages the præ systolic murmur frequently, if not always, vanishes, a short, sharp first sound or a systolic murmur alone being audible. At the same time the accentuation of the pulmonary second sound commonly disappears, owing to the development of tricuspid incompetence, which involves a reduction of blood-pressure in the vessels of the lungs.

In many cases of mitral stenosis no præ systolic or diastolic murmur can be detected, and a systolic apex murmur or a short, sharp first sound or a slight "prefix" to the first sound may be the only auscultatory evidence of mitral disease. The systolic murmur is frequently accompanied or preceded by a short thump, which some regard as the last portion of a præ systolic murmur, but which is more probably the modified first sound of mitral stenosis. When, in cases of this sort, the second sound is reduplicated and the systolic murmur is not well conveyed towards the axilla and back, the existence of mitral stenosis is very probable, and the degree of incompetence is slight. Reduplication of the second sound is more common in mitral stenosis than in any other condition, but this sign cannot be regarded as pathognomonic of mitral narrowing. A cantering rhythm, or "bruit de galop," in which three indistinct heart sounds are audible, is not uncommonly observed in this affection, but a similar rhythm may be developed in other diseases. It is easy to see why a systolic murmur should occur in mitral stenosis, owing to the incompetence which almost invariably co-exists, but it is not so easy to account for the numerous cases of combined stenosis and incompetence in which no systolic murmur is heard. The high tension in the pulmonary circulation and left auricle, as contrasted with the low pressure in the aorta, may explain the absence of a systolic murmur; for the blood in the left ventricle, flowing in the direction of least resistance, pours freely into the aorta, whereas the amount that escapes backwards into the distended auricle is comparatively trifling (Broadbent). The reduplication of the second sound is believed to be due to

asynchronous closure of the aortic and pulmonary valves, in consequence of the different degrees of tension existing in these vessels. The peculiar short, sharp first sound has been explained by the supposition that, the pressure in the left ventricle during diastole being very slight, the mitral valves are brought together with greater suddenness than in the normal condition, where the amount of blood entering the ventricle is larger and the curtains are floated up more gradually.

The præ systolic murmur may only be audible when the patient is in the recumbent position, and the examination of all doubtful cases in various postures is even more necessary in mitral stenosis than in any other form of valvular disease.

Pulse.—During the period of compensation there may be no appreciable change beyond perhaps a slight reduction in volume. In advanced stages the pulse becomes small and the tension usually falls. Occasionally the arterial pressure may be somewhat increased, possibly from the occurrence of vasomotor contraction in response to the imperfectly oxygenized state of the blood. When compensation fails the pulse frequently exhibits even more extreme degrees of arrhythmia than in mitral incompetence. Irregularity has been considered by many writers to be specially characteristic of mitral stenosis, and in the later stages this is no doubt perfectly true. But while compensation is preserved it is by no means common to find arrhythmia in this disease.

Derangement of the heart's rhythm in organic disease, as before stated, is largely the result of debility of the cardiac muscle, and secondarily of disordered innervation. Hence the development of arrhythmia is always a matter of importance, as it often conveys a timely warning.

The frequency of the pulse is generally somewhat increased even in compensated cases, and, when failure commences, the heart's action is almost always considerably accelerated. Beyond recording different varieties of arrhythmia the sphygmograph does not usually supply any information that cannot be obtained by other means.

Diagnosis.—A præ systolic murmur at the apex of the heart is the pathognomonic sign of mitral stenosis, but the severity of mitral obstruction is to be gauged mainly by the degree of enlargement of the right ventricle, by the amount of visceral engorgement and

by the volume of the pulse. Stenosis may be regarded as being less extensive when the two sounds of the heart are heard at the apex, in addition to the præsystolic murmur, than when the second sound is obscured at this point.

The quality of the murmur does not possess much significance, and it may be said that loudness of murmur in this as in all valvular disease points to hypertrophy, and therefore to compensatory changes.

VALVULAR DISEASE OF THE RIGHT SIDE OF THE HEART.—Primary affections of the valves of the right heart, except as the result of congenital disease, are almost unknown. Secondary lesions are less uncommon, especially in the case of the tricuspid valve.

V. Pulmonary Incompetence.—*Pathology.*—This, which is the rarest of valvular diseases, may depend on congenital abnormalities—*e.g.*, where there are only two semilunar valves, or in cases of acquired disease, it may develop in consequence of similar changes to those which occasion aortic incompetence. The small vegetations which not unfrequently develop on the pulmonary cusps in old-standing endocarditis of the left heart rarely give rise to functional derangement of the valve. Malignant endocarditis occasionally leads to pulmonary incompetence.

Effects upon the Heart and Circulation.—The effects of this lesion are seen in dilatation and hypertrophy of the right ventricle and to a less extent of the right auricle, and in distension of the systemic and portal veins. A patent foramen ovale and imperfect closure of the ventricular septum have been noted in some congenital cases. Communication between the two sides of the heart appears to be favourable on the whole, as the engorgement of the venous system is thereby diminished and the left ventricle receives a better supply of blood.

The *symptoms* proper to this very rare affection cannot be said to be well known, more particularly as emphysema, bronchitis and other pulmonary complications generally co-exist.

The *course* and mode of termination are the same as in severe disease of the lungs or of the mitral valve.

Physical Examination of the Heart.—The physical signs of pulmonary incompetence* are these:—Dilatation and

hypertrophy of the right ventricle, and a diastolic murmur in the pulmonary area, conducted down the left edge of the sternum to the ensiform cartilage.

The *pulse* is small and may be irregular.

Diagnosis.—The absence of signs of dilatation and hypertrophy of the left ventricle, and of a typical collapsing pulse, and the presence of the second sound in the carotid arteries are the chief points that may be relied upon to distinguish pulmonary regurgitation from incompetence of the aortic valves.

VI. Pulmonary Stenosis.—*Pathology.*—Stenosis may very occasionally be the result of chronic endocarditis or a growth of vegetations, but, with the rarest exceptions, it owns a congenital origin. This lesion may then be the result either of fetal endocarditis involving the valve segments, or of a ring-shaped fibrous thickening and contraction of the conus arteriosus (the portion of the ventricle immediately below the valves), or it may be a consequence of developmental malformation. The trunk of the pulmonary artery may be narrowed for a considerable distance beyond the valves, especially in congenital cases.

A patent foramen ovale, incomplete ventricular septum and persistent ductus arteriosus are very commonly associated with pulmonary stenosis. It is impossible to enter into the details of these conditions here, as the interest and importance which they possess are rather anatomical than clinical.

Effects upon the Heart and Circulation.

—The effects of stenosis are practically the same as in the case of incompetence of the pulmonary valves.

When stenosis is extreme, and when atresia or actual occlusion exists, the right ventricle may be small and undeveloped. In such cases death generally occurs soon after birth.

Symptoms and Course.—The symptoms of pulmonary constriction are mainly dyspnoea and varying degrees of cyanosis. When the lesion is congenital the disposition to cyanosis, particularly on exertion, is usually very marked, and the fingers and toes are often extremely clubbed. The patients rarely live more than ten or twelve years, though in a very few exceptional instances life has been prolonged to a comparatively advanced age. The growth of the body is always more or less interfered with, and the subcutaneous fat and muscles are imperfectly developed. In severe cases dyspnoea and cyanosis appear

* Cf. a case of this description with post-mortem examination by Sir Dyce Duckworth, (*lin. Soc. Trans.*, vol. xxi., 1888. The patient was a male, aged forty-nine.

directly after birth, but occasionally these symptoms do not develop till about the period of puberty.

The course of the disease is nearly always progressive, the patients generally succumbing to pulmonary complications.

Complications.—It is a remarkable fact that the subjects of this affection are very liable to contract chronic pulmonary tuberculosis.

Physical Examination of the Heart.—Physical examination reveals signs of enlargement of the right ventricle and a systolic murmur in the pulmonary area. The murmur is often harsh and audible over the whole præcordia, but at times it may be very faint. The point of maximum intensity is situated close to the left margin of the sternum, in the second intercostal space or at the level of the third rib. The murmur is not conveyed along the aorta into the carotids, but is generally propagated upwards towards the left clavicle, and may sometimes be heard over the back. The pulmonary second sound is weak, and when incompetence exists there may be a diastolic murmur.

A systolic thrill in the pulmonary area is commonly present.

In some cases of pulmonary stenosis no systolic murmur can be heard.

The *pulse* is weak, small, and may be irregular.

VII. Tricuspid Incompetence.—

Pathology.—This affection may be the result of endocarditis or of dilatation of the right ventricle and tricuspid orifice. In the former case the valvular derangement is produced by similar changes to those that have been described under the head of *Mitral Incompetence*, and the tricuspid lesion is almost invariably secondary to endocarditis of the left heart. Relative incompetence is far more common, and may supervene not only on affection of the mitral and aortic valves, but also on dilatation and debility of the left or right ventricle from whatever cause.

Effects upon the Heart and Circulation.

—Tricuspid incompetence leads to dilatation and hypertrophy of the right ventricle and auricle, distension of the systemic and portal veins, and ultimately to cyanosis and dropsy. This valvular defect can only be very imperfectly counterbalanced by hypertrophy and dilatation of the right ventricle and auricle; hence compensation is never adequate, and a condition of venous engorgement and arterial anæmia are

rapidly induced. The development of tricuspid insufficiency, therefore, greatly aggravates the effects of any existing valvular disease, and is always a matter of considerable gravity.

Symptoms and Course.—The symptoms of the tricuspid affection are almost always merged in those of the primary disease, and are represented by an increased tendency to venous stasis, cyanosis and dropsy. Where incompetence is relative, recovery may take place if the obstruction to the intracardiac circulation in front can be removed or diminished. Regurgitation due to structural changes in the valve is a most serious condition, and generally proves fatal at an early date, the mode of termination resembling that of mitral disease.

Physical Examination of the Heart.—

The physical signs of incompetence of the tricuspid valve are :—A systolic murmur heard loudest over the ensiform cartilage or at the lower end of the sternum, signs of enlargement of the right ventricle and weakening of the pulmonary second sound. The jugular veins are overfilled, and often exhibit systolic pulsation.

When the veins become stretched beyond a certain point their valves give way, and the regurgitant wave, entering the right auricle from the ventricle, passes into the jugulars, which therefore pulsate synchronously with the ventricular systole. If the degree of regurgitation be small, or if the ventricle contract feebly, venous pulsation may be absent. Incompetence of the jugular valves may be detected by compressing the vein high up in the neck and observing that it fills from below. The enlarged jugular veins may also show slight oscillations when their valves are intact and when no tricuspid incompetence exists, owing to the contractions of the auricle or ventricle being transmitted to the column of blood in the distended veins. The oscillations may therefore be either præ systolic or systolic. It is believed that the systolic expansion of the aorta may be communicated to the vena cava superior, and from thence to the innominate and jugular veins. If the veins pulsate strongly, and if their valves be incompetent, tricuspid insufficiency probably exists, but systolic jugular pulsation is not pathognomonic of this valvular lesion. The regurgitant stream, entering the right auricle, is also transmitted through the vena cava inferior to the hepatic

veins, which have no valves, and the liver sometimes can be felt to undergo systolic expansile pulsation, which is not to be confounded with the communicated pulsation which is so common in this region.

Pulse.—The pulse of tricuspid incompetence is small, weak, and frequently irregular.

VIII. Tricuspid Stenosis.—*Pathology.*—This condition is far more rare than incompetence, and, except in a few instances when it is congenital and associated with other malformations of the heart, it is always secondary to valvular disease of the left side, and almost invariably to mitral stenosis.

The effects of the lesion are very similar to those of tricuspid incompetence, and compensation is impossible.

The symptoms and course of the disease may be inferred from the description contained in the last section.

Physical Examination of the Heart.—A præstolic murmur, heard best over the ensiform cartilage, or somewhat to the left or right of this point, is the characteristic physical sign.

A thrill, præstolic in time, may occasionally be felt in the same position.

IX. Combined Valvular Disease.—The frequent association of stenosis and incompetence of the various valves has been emphasized more than once, though for the sake of convenience the individual affections have been considered separately.

The presence of these combined lesions is indicated by the *physical signs* proper to each.

The *diagnosis* of combined valvular disease turns not merely on the presence of the different characteristic murmurs, but also upon the secondary effects of the individual lesions on the heart and circulation generally. For instance, a small pulse in a case presenting the typical signs of aortic regurgitation should always suggest the possibility of concomitant mitral disease, even when the auscultatory evidence of the latter is equivocal or wanting. But though two or more lesions may be present in a given case, it should be stated that one frequently preponderates to such an extent as to claim almost exclusive attention.

It is worthy of note that the more chronic contractile forms of endocarditis, as a rule, lead ultimately to narrowing in the case of the mitral valve, and to incompetence when the aortic valves are concerned. The combination

of these opposite conditions of the two sets of valves is by no means rare. The frequency with which relative mitral incompetence develops in cases of aortic regurgitation has been already alluded to.

PROGNOSIS OF VALVULAR DISEASE.

—The prognosis is more favourable in aortic stenosis than in any other variety of valvular disease, owing to the marked preponderance of hypertrophy over dilatation in this affection. Incompetence of the aortic valves is a much more serious lesion, by reason of the great degree of ventricular dilatation which it occasions, together with its tendency to sudden death. Compensation is often preserved for years in both forms of aortic disease, but failure is less readily recovered from than in affections of the mitral valve. The relative prognosis in mitral stenosis and incompetence is still a matter of dispute. For practical purposes the prognosis is determined by the features of each individual case, and must be based on considerations common to all forms of valvular disease, which may be thus briefly summarised:—

State of the Heart's Wall.—The degree of enlargement and the relative proportions of hypertrophy and dilatation supply information as to the severity of the lesion and the capabilities of the cardiac muscle. Persistent arrhythmia is significant of myocardial degeneration. A history of repeated rupture of compensation suggests the probability that the cardiac muscle is becoming exhausted.

Extent and Nature of the Valvular Lesion.—The data required for estimating these points have already been mentioned in speaking of the several affections of the valves. When the lesion is extensive, and especially where it is presumably due to atheromatous changes, the prospects are serious. Degenerative vascular disease is necessarily progressive, and there is more danger of coronary obstruction, and therefore of myocardial degeneration.

Effects of the Lesion on the Circulation.—The condition of the pulse, the presence or absence of cyanosis and visceral stasis on the one hand, and of definite cardiac symptoms on the other, are the points that require special attention.

Condition of the Arteries and Viscera.

—Arterial degeneration adds to the gravity of the case, not only on account of the danger of cerebral hemorrhage, but also by reason of the increased

work which it throws on the left ventricle.

Persistent signs of hepatic and gastrointestinal derangement, albuminuria and passive bronchial catarrh, furnish evidence of serious disorder of the circulation, and are bad omens owing to the prejudicial effect on the general health which these conditions involve.

State of General Nutrition.—Anæmia and malnutrition are very apt to develop in all serious cardiac disease, owing to the baneful results of imperfect aëration of the blood and of the visceral derangements just alluded to. Preservation of a good standard of general nutrition is a favourable prognostic sign.

Social Condition and Habits of the Patient.—Laborious occupations, insufficient food, anxiety, worry, or mental overwork, sexual excesses, the abuse of alcohol, tobacco, tea, or coffee, have a most injurious effect. If these unfavourable influences can be excluded, the patient's prospects are immensely improved.

Age of the Patient.—The prognosis is always serious in children before the age of puberty, owing to the strain thrown on the heart during the active growth of the body. In old people the natural tendency to degenerative changes is apt to intensify the effects of valvular disease.

Complications.—The presence or absence of complications is a matter of much importance, but it must not be forgotten that in the most favourable and uncomplicated cases serious accidents, such as cerebral embolism, may occur at any moment, and may disarrange all previous calculations.

TREATMENT OF VALVULAR DISEASE.
—The preventive treatment of valvular disease at present is very unsatisfactory. The use of salicylic acid and its salts is generally believed to have little influence in hindering the occurrence of endocarditis, but nevertheless subacute relapses of rheumatism ensuing in the course of established valvular disease should always be promptly and carefully treated by rest and suitable drugs, as such outbursts are very apt to be associated with the development of a fresh crop of vegetations. In the case of valvular affections secondary to arterial disease we may hope for more results from prophylactic measures, considering the close relationship that subsists between atheroma and such influences as over-exertion, alcoholism, gout, and syphilis.

Stage of Compensation.—During this period drugs are seldom required, and treatment should be mainly prophylactic and hygienic. Patients should avoid excesses of all kinds, whether physical, mental, emotional, or sexual. The diet should be moderate, but nutritious and digestible. Wine or beer in small quantities may be allowed unless the tension of the pulse be high, in which case alcohol should be altogether eschewed. Tobacco, from its weakening action on the heart, must be used with great moderation. Warm clothing, and especially flannel next the skin, should be worn. Prolonged immersion in cold or hot water, and Turkish baths must be forbidden. Regular gentle exercise, gradually increased, is of great service on account of its beneficial effect on general nutrition and on the coronary circulation. As long as the patient experiences no dyspnoea, walking, riding and shooting, may be indulged in with advantage. In persons of sedentary habits still greater caution is required, and physical exertion must be more carefully undertaken.

The intelligent co-operation of the patient is especially needed during the stage of compensation. On the one hand, he should be informed, as far as it is thought advisable, as to the general nature of his complaint; but on the other, it is quite as important to avoid unnecessary plainness of speech, as the moral effect of being told that he is the subject of "heart disease" often takes all heart out of the patient. He should be encouraged to believe that his future is to a large extent in his own hands, and his rule of life should be "moderation in all things." Regular daily evacuation of the bowels must be secured, and in plethoric patients an occasional course of saline aperients or some corresponding mineral water may be ordered. A tendency to anæmia is an indication for iron or some chalybeate water. Functional disorders must be treated in the usual way. Sea air and health resorts at moderate elevations as a rule suit most cardiac cases, but others are sometimes benefited by a sojourn at some of the Continental or English Spas. Oertel's system of treating cardiac disease by mountain climbing has not found much favour in England, and is probably more suited to cases of moderate non-valvular enlargement of the heart, in which obesity is a prominent feature.

The question of marriage is a most important one. Women should, if possible be prevented from marrying on

account of the great risks attendant on pregnancy and parturition. In the case of men marriage may be sanctioned if compensation be satisfactory, and when there is reason to believe that the cardiac affection is likely to be stationary. At the same time, the probability that the ordinary expectation of life will not be realised must be taken into consideration.

Stage of Failing Compensation.—When dilatation and cardiac weakness begin to predominate, a careful combination of specific cardiac remedies, with other measures both general and local, is called for. In the first place, complete rest in bed must be insisted upon. Light nutritious food should be given in small quantities and at short intervals, and a regular action of the bowels must be secured.

Among cardiac drugs none can compare with digitalis for general usefulness.

The effect of *digitalis* is exerted both on the general circulation and on the heart itself. On the one hand it raises the tension in the arteries, and on the other it slows the action of the heart, and increases the force of the individual contractions. Failure of the heart's contractile power, with signs of dilatation, low arterial pressure, and a small and rapid pulse, are therefore the special indications for the use of digitalis. The good results of this medicine are more conspicuous in mitral than aortic cases, and objections have been raised to its use in aortic incompetence, on the ground that the lengthening of the diastole leads to still further distension of the left ventricle, and the increased force of the cardiac contractions, coupled with heightened arterial tension, adds to the risk of cerebral hæmorrhage. Against this view it must be stated that during the period of cardiac dilatation an increase in the force of the ventricular systole, and a rise of arterial pressure, are of great advantage, inasmuch as the arteries are always more or less empty between the beats—*i.e.*, the mean pressure is low, even in fairly well compensated cases of aortic regurgitation, and when the left ventricle begins to fail the arteries are of course even less adequately filled. And it must be remembered that a steady and continuous flow of blood through the capillaries, which is the end and object of the circulation, is determined, not by the initial, but by the mean pressure in the arteries.

If the use of digitalis be strictly

limited to the stage of progressive dilatation, its results are often most satisfactory; at the same time it should be administered with great caution and in small doses to begin with in aortic disease, and as soon as its tonic effects on the heart are obtained it should be discontinued. The beneficial action of the drug is also manifested in the relief of visceral congestions and their consequences—dyspnoea, bronchitis, deficient secretion of urine and dropsical effusions.

In mitral cases, where dilatation is pronounced, the infusion in doses of 2 to 6 drachms, or an equivalent amount of the tincture or powder, may be ordered every three or four hours for a few days until the effects of the drug appear, medicinal treatment being then suspended for a time altogether. Owing to the so-called cumulative action of digitalis, symptoms of poisoning sometimes develop with very little warning. When, therefore, a patient complains of nausea or vomiting, and the pulse becomes weak, small, and irregular, and the quantity of urine declines, the drug must be at once stopped, and if collapse be threatened, brandy, ether, and ammonia should be exhibited till the heart's power is restored. In some cases the maximum effects of digitalis are not obtained for twenty-four hours or more after its administration has been suspended. Diuresis and removal of oedematous swellings are among the most striking and tangible results of its successful action. The increased flow of urine is to be attributed to stimulation of the heart's contractions, and to a rise of pressure in the renal artery.

The use of digitalis in smaller doses, continued for a longer time, is to be preferred in other cases, but here also the physician must be on the watch for nausea and other toxic symptoms. At times gastric symptoms are so persistently produced that the remedy has to be abandoned. Occasionally a change to another preparation obviates the difficulty. It may here be repeated that rest is of the first importance, and in many instances of cardiac failure, especially among the poor, a few days in bed, with suitable food, suffice to restore a considerable degree of compensation.

It is very common to meet with patients who are, so to speak, on the borderland between compensation and failure, to whom digitalis in tonic doses of 10 minims of the tincture twice a day may be administered continuously for

weeks and months with the greatest advantage.

Iron may be combined with digitalis if anæmia be a prominent feature; otherwise the latter drug is better given alone, owing to the liability of iron to cause constipation. When the action of digitalis begins to fail, it may generally be inferred that the limits of compensatory hypertrophy have been reached, this result depending on the progressive nature of the valvular lesion, or on the supervention of myocardial degeneration.

Strophanthus, introduced by Fraser, closely resembles digitalis in its action, and though less generally useful, it sometimes proves an efficient substitute when the action of the latter remedy is becoming exhausted. *Convallaria*, *adonis vernalis*, and various other drugs have been recommended as possessing similar virtues, but experience has scarcely confirmed these expectations.

Strychnine, ether, and ammonia are also valuable remedies, and may be employed in all valvular affections to stimulate the action of the heart.

Belladonna is sometimes serviceable in aortic cases, and in combination with digitalis it may be advantageously prescribed in mitral disease, especially when arrhythmia is a prominent feature.

TREATMENT OF SPECIAL SYMPTOMS.
—*Dyspnœa*, when it depends upon engorgement of the pulmonary circulation, can only be relieved by improving the force of the heart (digitalis, strychnia, &c.). When it is due to bronchitis, expectorants may be combined with digitalis. The dyspnœa which occurs in connection with high arterial pressure may often be relieved by nitrite of amyl and nitro-glycerine. The last-named remedy is occasionally useful in those exceptional cases of mitral stenosis where the tension of the pulse is raised. Small hypodermic injections of morphia sometimes give great relief when all other measures fail.

Palpitation in cases of failing compensation is usually symptomatic of cardiac weakness, and here the administration of small quantities of brandy, frequently repeated, is sometimes successful. A belladonna plaster, or an ice-bag applied to the præcordia, and bromide of ammonium, may also be tried.

Cardiac pain is often benefited by arsenic, iodides, or nitro-glycerine. Local applications of belladonna and aconite are also useful.

Dropsy may be treated by diuretics, such as digitalis, caffeine, convallaria, sparteine and squill, but of these digitalis is by far the most effectual. The combination of digitalis, squill, and blue pill is sometimes of great service. Calomel in repeated doses has lately been found to act well as a diuretic in cardiac cases.

Hydragogue cathartics are often used for the same purpose, though they have a less decided effect than diuretics. Jalap, scammony, elaterium, acid tartrate of potash, and mercurial preparations are the drugs that are mostly employed. Edema of the skin may be relieved by puncture with Southey's trocars, but great cleanliness and antiseptic precautions are needed to prevent the development of erysipelas and other inflammatory affections.

Deficient secretion of urine must be treated by remedies, like digitalis, that act on the renal circulation.

Insomnia, which is often a most distressing symptom, may at times yield to paraldehyde, urethane, sulphonal, and bromides, but in troublesome cases a small hypodermic injection of morphia is the only means by which sleep can be obtained. A course of belladonna has occasionally been found by the writer to give good results.

Dyspepsia, being commonly the consequence of portal congestion, is usually benefited by mild purgatives, in combination with bitter infusions, acids, or alkalies, in different cases.

Hæmoptysis is most common in mitral stenosis, and though it alarms the patient, its effect is often salutary, and no special treatment is required.

Syncopal attacks are prone to occur in aortic cases as the result of cerebral anæmia. Brandy, ether, and ammonia may be administered, and the patient should be placed flat on the back.

The treatment of complications such as embolism, effusions into serous cavities, &c., must be carried out on general principles. The preceding remarks refer more especially to disease of the aortic and mitral valves, but affections of the right side of the heart must be treated on the same principles as those recommended in the case of mitral disease. In combined valvular affections treatment must be directed to the predominant lesion.

PERCY KIDD.

HEARTBURN is a prominent symptom of chronic gastritis, and

consists of a burning sensation generally referred to the cardiac end of the stomach, but sometimes felt all over the abdomen. Acid eructations are usually present. Careful dieting is of the first importance in the treatment. Fat, sugar, starch, and beer should be prohibited, very weak brandy-and-water being the only stimulant allowed. Alkalies may be administered with benefit.

HECTIC FEVER means literally habitual fever, but the term is now used to denote the chronic fever met with in certain wasting diseases, especially those of a tubercular nature. The temperature usually attains its maximum in the evening, and there are very marked remissions or complete intermissions in the morning. Emaciation, pallor, and night sweats are the usual accompaniments of hectic fever; often there is a bright circumscribed flush on one or both cheeks: this is known as the hectic flush.

HEMIPLEGIA.—Paralysis of one-half of the body, the result of a lesion existing in the *opposite* half of the brain.

Hemiplegia may be caused by—(1) extensive disease of the motor part of the cortex; (2) lesions of the motor fibres of the corona radiata, passing down from the cortex; (3) disease about the corpus striatum, involving the motor fibres of the internal capsule contiguous to it; (4) a lesion of the pyramidal tract in the crus cerebri and pons Varolii.

The most common cause of hemiplegia is hæmorrhage or softening about the internal capsule and corpus striatum, but although the corpus striatum has been usually described as the seat of hemiplegia, it seems probable that lesions of this body alone do not cause hemiplegia unless the internal capsule itself be involved. The portion of the internal capsule, destruction of which causes hemiplegia, comprises a small part of the anterior limb just in front of the genu and the anterior two-thirds of the posterior limb. Hemiplegia with gradual onset is also caused by tumours occurring in the above-mentioned parts of the motor tract.

Symptoms.—When, after an attack of apoplexy, the patient attempts to move the limbs, he is frequently found to be paralysed in one-half of the body. In the early stage of such an attack the patient may have conjugate deviation of the eyes, and the head may be turned towards the sound side (by the over-

action of the non-paralysed muscles), and there may be some difficulty in turning the head and eyes towards the paralysed side.

The naso-labial fold is less marked, and the angle of the mouth is lower, on the paralysed side, and there is difficulty in showing the teeth on that side; the upper part of the face is usually unaffected though in some cases there may be rather more difficulty in wrinkling the brow and in closing the eye on the paralysed side, but never to the extent observed in paralysis of the trunk of the facial nerve. The tongue, when protruded, deviates towards the paralysed side, the speech is sometimes thick and indistinct, and with right hemiplegia aphasia may be present. Slight difficulty of swallowing may exist.

The upper and lower limbs of the affected side are completely or partially paralysed, and at first are relaxed or may present the phenomenon of "early rigidity"—a condition supposed to be due to "irritation" by the lesion of the neighbouring parts of the brain.

The muscles of the paralysed limbs react well to both faradic and galvanic currents, and there is no loss or change of reaction such as is seen after lesions of the anterior cornua of the spinal cord or of the peripheral nerves. There is no marked wasting of the limbs, and no anæsthesia, unless the sensory fibres in the posterior third of the hinder limb of the internal capsule be involved. The tendon-reflexes are increased on the paralysed side, the knee-jerk (patellar-tendon reflex) being increased, and ankle-clonus being present, while the superficial reflexes (plantar, &c.) are usually diminished. The sphincters are not involved as a rule, unless there be some mental defect owing to the highest cerebral centres being involved, or in cases of double hemiplegia. The thoracic muscles and abdominal muscles escape paralysis, but at times the abdominal muscles are weak on the paralysed side.

After a few days, weeks, or even months, a gradual return of power takes place in the paralysed limbs, and in most cases the leg begins to recover before the arm, and the proximal joints of the limbs (shoulder, hip) before the distal ones (hand, foot). If the attack have been a slight one, the patient may completely recover the use of his limbs, but in a great many cases a certain amount of power returns in the shoulder and elbow, but not in the hand or wrist.

After a few weeks, the joints which fail to recover power are affected with "late rigidity," and become stiff and contracted, while at the same time the tendon-reflexes are much increased. The rigidity is due to sclerosis descending from the fibres which have been destroyed in the internal capsule down the pyramidal tract and lateral columns of the spinal cord.

In some cases the face and the upper limb are affected, and the lower limb escapes, whilst in others the lower limb is affected more than the upper, and here it is often noticed that the face is very little paralysed, and recovers very soon, while the arm recovers power before the leg. The writer considers that these cases are due to the lesion occurring in different parts of the internal capsule or the cortex, the anterior region of the motor part of the capsule being affected in the former case, and the posterior part in the latter.

In lesions about the upper part of the pons Varolii the third nerve on the *same* side as the lesion is liable to be paralysed, producing external strabismus of the eye, with ptosis—along with hemiplegia of the side *opposite* to the lesion; and in lesions of the lower part of the pons the facial nucleus of the *same* side as the lesion may be affected—causing paralysis of the whole of the face of that side, with paralysis of the arm and leg of the opposite side; this is called "cross paralysis."

With hemiplegia there is frequently hemianæsthesia of the paralysed limbs, the loss of sensibility being sharply limited by the median line. In such cases there is sometimes hemianopsia of the same side—*i.e.*, with right hemianæsthesia, the right half of the field of vision for both eyes is abolished, with loss of hearing, taste, and (?) smell on the same side as the hemianæsthesia.

Dr. Broadbent explains the paralysis of the face, arm, and leg, and the exemption of the chest and abdominal muscles, by supposing that, as both sides of the chest and abdomen are in the habit of acting together, their spinal nuclei are very intimately connected, and that both sides can be stimulated by either cerebral cortex; whereas the hand and foot are so specialised that they can only be stimulated from the cortex through their own particular spinal cells of the same side.

Diagnosis of the cause of the attack is considered under the heading of CEREBRAL HÆMORRHAGE.

With regard to the position of the

lesion producing the hemiplegia it may be said that lesions of the cortex are usually associated with epileptiform convulsions of one side, occurring during the course of the hemiplegia, and affecting the paralysed limbs (*see BRAIN, TUMOURS OF*). In such cases the paralysis is often partial and affects the face alone, or one limb only. Lesions about the pons Varolii are shown by the cranial nerves of that region being involved on the opposite side to that of the limbs.

The most common site of the lesion is in the internal capsule. It is difficult to diagnose this from disease of the corona radiata, but to produce the same amount of paralysis a much larger lesion would be required there, owing to the spreading out of the motor fibres.

Hemianæsthesia usually means that the posterior part of the internal capsule is involved, but it may be also caused by lesions of the pons Varolii.

Prognosis is bad if there be no return of power in the paralysed parts at the end of a month. Early rigidity is an unfavourable sign, especially so if it persist. When, after several weeks, there is no return of power in a limb, such as the arm, and it becomes stiff from late rigidity, with great increase of the tendon-reflexes, it is almost hopeless to expect any improvement. Hemiplegia, with a gradual onset, especially in old people, is unfavourable, as it is frequently due to softening from thrombosis. In cases in which the onset is gradual, and signs of an intra-cranial growth subsequently develop, the prognosis, is of course, very grave.

Treatment.—In the early stages of hemiplegia the patient should be kept completely at rest in bed, and the bowels attended to. The diet should be light and nourishing, and stimulants are best avoided. Later on the paralysed limbs may be rubbed, and passive moments employed, and the patient encouraged to try and move them. To prevent wasting the muscles should be faradised, but not at the outset of the case. Tonics, as quinine and iron, are useful, and nerve tonics, as strychnine and hypophosphite of soda, may be given with advantage. A history of syphilis will suggest the use of iodide of potassium and mercury. As soon as the patient is well enough he should be got into a couch or wheeled chair, and encouraged to walk when sufficient power has been regained in the leg.

C. E. BEEVOR.

HERPES is an acute inflammatory affection, characterised by the development of groups of vesicles on a patch of inflamed skin or mucous membrane.

Two forms are recognised, which, although similar in their anatomical characters, differ as regards their clinical phenomena and pathological relations.

I. *Herpes Catarrhalis* frequently follows a rigor, and may be its sole sequela. In children a pyrexia of two or three days' duration and of considerable intensity (103° – 104° F.) may rapidly subside on the appearance of a crop of herpes. "Herpetic fever" is sometimes a prominent feature of "catheter fever," and often accompanies the onset or crisis of acute febrile diseases, especially pneumonia, pleurisy, bronchitis, ague and enteric fever. It is commonest in spring and autumn, and may affect so many persons simultaneously as almost to merit the epithet epidemic. The lesions do not exhibit the "nerve distribution" and unilateral distribution of those of zoster. It is accompanied by little or no pain, seldom leaves scars, and is very prone to recur.

Herpes facialis is the commonest form. It occurs in order of frequency upon the lips, *alae nasi*, ears, chin, and cheeks, and often spreads to the mucous membrane of the cheek; more rarely the tongue, soft palate, uvula and tonsils are attacked, especially in connection with digestive derangements ("dyspeptic ulcers"). The vesicles on the skin are small, contain clear or turbid fluid, do not rupture unless interfered with, cause no subjective symptoms except slight burning sensations, and usually dry up, with the formation of yellowish crusts, in about a week. On the mucous membranes, however, minute excoriations result from the maceration of the epidermic covering of the vesicles by the saliva, and may lead to a mistaken diagnosis of aphthæ, diphtheria, or even syphilis.

Herpes progenitalis is common in the male sex, affecting chiefly the prepuce and glans penis, but is rare in the female sex, with the notable exception of "*puellæ publicæ*," in whom it is common, and situated generally upon the *labia majora* and *minora*. In both sexes antecedent syphilis or gonorrhœa predisposes to its occurrence; it is very liable to recur, and in some individuals every act of coitus is followed by an outbreak. It seldom occurs in persons above forty years of age. The vesicles are rarely numerous, and, if left alone,

heal in a few days; but they are often scratched, when the resulting excoriations may discharge freely, and the diagnosis from chancroids may become extremely difficult. Sometimes severe neuralgic pain is present, allying the disease with zoster.

Treatment.—Dusting powders or soothing ointments are usually all that is required, but lead lotions may be used if there be much burning or pain.

II. *Herpes Zoster* (*Zoster*, *Zona*, *Shingles*) is the result of neuritis, most commonly of the intercostal and lumbar nerves, and follows their peripheral distribution.

The two upper divisions of the fifth nerve are also frequently affected, when the cutaneous manifestations may be accompanied by conjunctivitis, keratitis, iritis, or even papillitis. It may, however, follow the course of any cutaneous nerve, various names being attached to it indicative of the nerve or region affected. The nerves most frequently involved are the sciatic, anterior crural, ilio-inguinal, musculo-spiral, occipitals and the branches of the superficial cervical plexus. It is almost invariably unilateral, and, if bilateral, the same nerve is never affected on the two sides. A symmetrical herpetiform rash affecting the distribution of both fifth nerves has, however, been observed in some syphilitic cases. Recurrences are said to be very exceptional, but the writer's experience does not support the statement.

The appearance of the rash is generally preceded by severe neuralgic pain, lasting twenty-four hours or more, and frequently by considerable febrile disturbance or malaise. Then patches of skin inflame, and closely packed clusters of small papules, which rapidly become vesicles containing clear fluid, form upon them. At the end of four or five days the climax of the disease is usually attained, but successive crops may sometimes appear afterwards. The fully developed vesicles are often about the size of a pea, and may coalesce to form large, shallow blebs, the contents of which may be serous, purulent, or hæmorrhagic. At the periphery of the patches the lesions frequently abort—*i.e.*, are arrested in an intermediate stage of their development. The eruption after attaining its maximum quickly subsides, yellow scabs being formed, the separation of which often leaves deep, indelible scars. The process is generally complete at the end of three weeks, but sometimes, owing to extrinsic

circumstances, the lesions become gangrenous, and healing is protracted.

Pain is a prominent feature of the disease, except in children; it may precede, accompany, or succeed the rash, and bears no proportion to its amount; in old persons it is often of excruciating intensity, and may persist for months after apparent recovery. There may be anæsthesia or numbness of the skin, even where subjective pain is complained of (anæsthesia dolorosa). Persistent pruritus, motor paralysis, and atrophy of skin or subjacent muscle are rarer sequelæ.

The *diagnosis* is easy as a rule, but difficulties may arise from the eruption being abortive or becoming irritated by rubbing, scratching, or unsuitable applications. It may be mistaken for pleurodynia or pleurisy at first, afterwards for vesicular or pustular syphiloderma, eczema, hydroa, or pemphigus.

Pathology.—Inflammatory changes have been demonstrated in the spinal ganglia and peripheral nerves. Vesication results from the rapid and copious exudation of serum and leucocytes into the loose rete mucosum, raising the epidermic layers; scars are the consequence of the destruction of the papillary layers.

The *ætiology* of most cases is obscure; cold, damp, and malaria are responsible for a certain number, and small epidemics often occur in spring and autumn. Injuries to, pressure upon, and various diseases of, the nerve trunks and centres may cause herpes in certain persons, and it is believed by some, and probably with reason, to occur with special frequency during the administration of arsenic.

Treatment.—The part must be protected from friction and irritation by dusting powders (zinc or bismuth oleate, starch, &c.), and cotton wool. If pain be severe, morphia and collodion is a useful application. Tonics must be given, especially quinine, iron, and cod-liver oil. Phosphide of zinc ($\frac{1}{3}$ grain every three hours) is said to shorten the disease. For persistent pain camphor-chloral, belladonna liniment, and galvanism have been warmly recommended, but morphia used hypodermically is the most reliable drug, and one injection occasionally gives permanent relief. The diet ought to be generous, and, in the case of old persons, may include good wine.

J. J. PRINGLE.

HICCOUGH (Hiccup; Singultus) is a sudden contraction of the diaphragm,

unaccompanied by the normal simultaneous opening of the glottis.

Hiccough is a reflex act, but the term is commonly applied to the characteristic noise due to the inrush of air through the narrowed glottic opening, which necessarily attends it, and is its most obvious feature. It is met with in many forms of nervous and gastric disorder, in uræmia, and in abdominal diseases, especially peritonitis, when it is of decidedly unfavourable omen. Even when it has no such significance it is certainly a troublesome symptom to the patient.

Treatment.—Holding the breath is a popular and frequently efficacious method of arresting it. In serious cases the stomach should be emptied by an emetic. If that be inadvisable, a subcutaneous injection of morphia may be given. When due to a nervous affection, chloroform and opium may be tried.

HYDATID DISEASE.—An hydatid tumour consists of one or more cysts enclosed in a fibrous capsule, and originating from the scolex of the tænia echinococcus, a form of tapeworm which infests some of the lower animals, and notably dogs.

The adult worm is very small, measuring about a quarter of an inch in length, and possessing only four segments, of which the terminal one is as long as the rest of the animal, and is alone provided with reproductive organs. The head presents four suckers and a double row of hooklets, varying from thirty to fifty in number. The eggs, discharged with the terminal segment, find their way into the human stomach, and, their capsules being dissolved, the embryos, armed with six hooklets, are set free, and, having made their way through the coats of the stomach, may wander to any part of the body. As they are far more often met with in the liver than elsewhere it may be presumed that they get into one of the branches of the portal vein.

Arrived at its destination, the embryo loses its hooklets, increases in size, and becomes converted into a transparent vesicle. The next change is that a granular layer forms around it which is converted into fibrous tissue, ultimately constituting its capsule. Inside this the cyst-wall proper consists of two parts, an outer thick homogeneous laminated elastic membrane, and an inner granular layer. From this inner layer there protrude inwards many little bud-like cysts, which for a time remain

connected to it by a pedicle, but are ultimately set free, and are then known as daughter cysts. Inside these by a similar process other cysts may form (grand-daughter cysts). When the pedicles do not disappear, and the buds remain permanently attached to the inner layer, they are known as brood capsules, because they contain the scolices, of which there may be ten or a dozen in each little sac. The scolex is the larval form, and possesses a head exactly resembling that of the parent worm.

The fluid contained in these cysts is clear, non-albuminous, and slightly saline. On microscopical examination, some detached hooklets will often be found in it, as well as the scolices. An echinococcus cyst may not develop any scolices, in which case it is spoken of as an acephalocyst. Very rarely the cysts are multilocular—*i.e.*, divided by septa into a number of small cavities.

The *symptoms* produced by the presence of an hydatid tumour will depend upon its situation, and will be found on reference to the diseases of the viscera most commonly affected (*vide* LIVER, HYDATID OF; ABDOMINAL TUMOURS, DIAGNOSIS OF).

JOHN ABERCROMBIE.

HYDROA.—This term includes a group of vesicular and bullous skin affections presenting many points of affinity with the vesicating erythemata on the one hand, with herpes and pemphigus on the other, but with characteristics of its own sufficiently marked to justify separate description. The group includes the diseases described as dermatitis herpetiformis, pemphigus pruriginosus, urticaria vesicans and herpes gestationis, and is by no means so uncommon as is generally supposed.

Hydroa occurs in persons of either sex, especially those of neurotic temperament, and often after worry or anxiety; frequently it shows itself during pregnancy or in the parturient state. Its course is intermittent and chronic, lasting for months or even years with periodical intermissions or exacerbations, but with a decided tendency towards ultimate recovery.

Symptoms.—Shivering, pyrexia, and malaise may precede its outbreak, and violent itching is almost invariable; then erythematous patches and raised papules or plateaux, often circinate and rapidly vesicating, appear in successive crops on the trunk and limbs, but the face, neck, scalp, and buccal mucous membrane may

also be affected. The vesicles, when recent, are small, pin-head sized, often angular, tense or umbilicated, contain clear or turbid yellowish fluid, and frequently exhibit herpetiform grouping. By their fusion large bullae may be formed, and these may or may not be surrounded by an inflammatory halo. These various types of lesion usually co-exist, giving the disease its markedly polymorphic character.

Itching is almost always severe throughout, and pain or burning is often also complained of. The formation of scales and crusts evidences the beginning of subsidence of the eruption, which is followed by deep pigmentation, with or without scarring.

The *diagnosis* is often difficult at first; the disease may be mistaken for variola, pustular syphiloderma, or bullous iodide rash; afterwards it must be differentiated from its afore-mentioned congeners.

Treatment is sometimes decidedly beneficial. Arsenic, pushed to the limit of the patient's tolerance, is the drug most generally useful. At other times belladonna, atropine, and quinine appear to be valuable, while cod-liver oil is of marked benefit to debilitated persons. Locally, lotions of liquor carbonis detergens (3ij ad ʒviii) or of thymol or naphthol (2 to 5 per cent.) are useful in allaying itching, but prolonged tepid bathing may sometimes be necessary to obtain a good night's rest.

J. J. PRINGLE.

HYDROCEPHALUS.—An accumulation or excess of fluid either within the cerebral ventricles (internal) or outside the brain substance (external). Analogous conditions occur about the spinal cord.

Symptoms.—The head grows large and becomes globular; the circumference of the head may be enormously increased, and may measure 30 inches; the rate of growth varies, and sometimes the head remains stationary in size for weeks together. The sclerotic is often exposed above the cornea, chiefly because of the altered plane of the orbital plates, their direction being much more vertical than natural. The unossified sutures readily yield before the hydrostatic pressure, and the bones become very thin, either generally or in limited areas (craniotabes, *q.v.*); in the sutures and fontanelles Wormian bones may develop. The sagittal suture and anterior fontanelle are normally later than other parts in closing, and those parts present most widening

and are the last to close in hydrocephalus.

The eyeballs are rendered more prominent and depressed, so that the pupils may be partly covered by the lower lids. A vibratile thrill or fluctuation may be detected. The hair often grows thinly; the skin of the head may be tense and shiny; large veins may cause furrows (simulating sutures) in the skull bones; the face looks abnormally small by contrast with the big cranium. The mental, motor, vaso-motor and trophic functions are very often deranged. Convulsions are not uncommon; the spasms may occur in any part of the body; they may partake of the characters of true epilepsy; twitchings sometimes like chorea may be seen. The muscles are always weaker than natural; their mechanical and faradic irritability is almost always increased. The knee jerks are usually exaggerated, and ankle clonus may be obtained; the superficial reflexes are sometimes increased, sometimes more marked on one side of the body. Sometimes there is great emaciation, and at others remarkable fattening (lipomatosis neurotica). Acromegaly has been noted in at least one case, and in one case myxedema may have been present, and the thyroid was atrophied.

The mental development is often retarded, though it is striking how intelligent many of these children seem. If hydrocephalus develop after closure of the cranial sutures, mental apathy and other obscure signs may occur, leading to a diagnosis of "tabes nervosa" or "neurasthenia." Probably any motor symptom and any mental symptom may occur in these cases; strabismus, nystagmus, amblyopia, contractures, laryngismus stridulus, and various paralyses have been observed. The optic nerves may be atrophied and white from pressure on the optic chiasma by the distended third ventricle.

The course is not usually favourable; most cases die within a few years, generally as the result of convulsions or intercurrent inflammation of the lungs or throat (diphtheria). There is nothing in the nature of the affection which should kill, bearing in mind that the brain tissues are singularly tolerant of slowly increasing pressure. Trousseau recorded a case which lived for seventy-eight years.

Diagnosis.—An encephalocele differs from hydrocephalus in being local and more opaque, and in having a doughy, clastic consistence. A fungus of the

dura mater projecting through a bone is also local and feels doughy. Macrocephalus or large head may be due to rickets or syphilis, and perhaps to a "hypertrophy" (probably false) of the brain. In the two former diseases the enlargement is chiefly due to bony overgrowth.

Pathology.—Probably most cases of chronic hydrocephalus are due to the interference with the circulation of cerebro-spinal fluid between the sub-arachnoid spaces and the cerebral ventricles, and probably also the most frequent cause of this interference is occlusion of the foramen of Magendie (see MENINGITIS, POSTERIOR); which is generally the effect of a local meningitis. Hydrocephalus arises also in cases of intracranial tumour, and the mechanism may be the same in all cases. That congenital syphilis may determine a *posterior meningitis* with subsequent hydrocephalus is certain. That rickets alone is capable of producing hydrocephalus is very doubtful.

Pressure on the venæ Galeni, impediments to the escape of blood by the veins and intracranial sinuses, excessive secretion or diminished absorption from the lining membranes of the brain are each quoted as effective in the production of hydrocephalus.

Anatomy.—The ventricles are distended with a serous fluid, which may be quite clear, turbid, or may contain flakes of lymph, and is in some cases purulent. All the soft parts of the brain are stretched and thinned, and the commissures and septum lucidum are generally torn and macerated (white softening). The sulci tend to be obliterated, and the convolutions to be flattened. The membranes may be thinned, but are often thickened, and they may present a "shagreen" appearance, granules, looking like fine white sand, studding their surface over a varying extent. These granules are composed of small round cells; they appear to be buds composed of granulation tissue (see *Path. Trans.* 1889—case by the writer of meningitis, arteritis, sclerosis and atrophy of the brain from congenital syphilis). It is possible that these buds are immature morbid choroid plexuses. The mode of origin of the choroid plexuses has not yet been clearly explained.

Ætiology.—Acute hydrocephalus internus occurs in tubercular and other forms of meningitis. External hydrocephalus is met with in cases of local atrophy of the brain; it is not usual to

describe as external hydrocephalus a general excess of fluid in the sub-arachnoid tissues of the brain such as goes with general cerebral atrophy. External hydrocephalus may accompany any sort of local brain atrophy, whether it be porencephalia—congenital hole in the brain—or the result of hæmorrhages, embolism, or thrombosis. Speaking generally, by hydrocephalus is meant a chronic dropsy of the cerebral ventricles, dating from birth or early infancy (congenital or infantile).

Treatment.—Great care is required to prevent the occurrence of accidents, as blows and falls are more apt to develop neuroses than when the brain is healthy. Counter-irritation and internal remedies scarcely ever cause any reduction in the quantity of fluid or affect the size of the head. Uniform pressure by strips of plaster or by bandaging, so as to make methodical compression, has very seldom done any good. Paracentesis is scarcely less hopeful, though in a few cases the head has been lessened in size; if the operation be undertaken, the fluid must be very slowly withdrawn, and even then convulsions may arise. The first spot to puncture is about an inch from the anterior fontanelle near the edge of the coronal suture, so as to avoid the longitudinal sinus and entering veins; only a few ounces of fluid should be withdrawn at one time; the difficulty as a rule is to get much fluid to flow through the fine cannula.

In syphilitic infants the inunction of blue ointment into the shorn scalp has removed the hydrocephalus in three of the writer's cases.

ANGEL MONEY.

HYDROMETRA means retention of watery fluid in the uterine cavity from blocking of the cervical canal.

It has been found on post-mortem examination as a result of congenital atresia in young infants; but it most commonly occurs in women who have ceased to menstruate. It is a result of endometritis, which is either combined with cicatricial closure of the cervical canal, or the canal is blocked by a tumour, or there is flexion of the uterus, flattening the canal at the point of flexion, and so closing it; the atrophied senile uterus being thin and deficient in contractile power. The condition is preceded by leucorrhœa, and sometimes the distension of the uterus is accompanied by pain, but it rarely causes troublesome symptoms, and may be only discovered

in post-mortem examination. It may lead to regurgitation of fluid into the tubes and their distension, *i.e.*, hydrosalpinx.

The *treatment* of hydrometra is simply to reopen the canal and let out the fluid. The opening should then be kept patent with a stem until its margins have healed. In cases of hydrometra due to flexion, the mere passage of a sound or a bougie is often sufficient.

G. E. HERMAN.

HYDROPHOBIA (RABIES).—It is unfortunate that the term "hydrophobia" has been generally adopted as the name of this disease in preference to "rabies," as a fear of water, although a prominent symptom of the disease in man, is absent in the lower animals.

Rabies is an acute disease due to the presence of a specific virus which is conveyed by inoculation from animal to animal (all being susceptible to its effects) by subcutaneous or submucous infection through a wound.

Virus.—This, though it has never been isolated in a pure state, behaves so exactly like an organism that there can be no doubt that it is one.

The virus is found almost exclusively in the nervous system, especially in the medulla and spinal cord. It is also contained (evidently in the process of excretion) in the secretion of certain glands, notably the salivary glands. It has been stated to occur in milk, but this has never been proved.

After the virus has been introduced into the system the period which elapses before the appearance of the symptoms depends upon the following factors:—

(a) *Age.*—The incubation is shorter in children than in adults. For obvious reasons the former are more frequently attacked.

(b) *Part Infected.*—The rapidity of onset of the symptoms is greatly determined by the part of the body which may happen to have been bitten.

Wounds about the face and head are especially dangerous; next in order of decreasing mortality come bites on the hands, then injuries to other parts. This relative order is no doubt greatly dependent upon the fact that the face, head and hands are usually naked, while the other parts are clothed; but bites about the head and face are under all circumstances the most dangerous.

(c) *The Extent and Severity of the Wound.*—Punctured wounds are the most dangerous, and lacerations are fatal in proportion to the extent of the surface afforded for absorption of the virus.

(d) *The Animal conveying the Infection.*—In order of decreasing severity come: (1) Wolf, (2) cat, (3) dog, (4) other animals.

The death rate among those bitten by wolves appears to be about 40 per cent.; among those bitten by dogs it is about 15 per cent. It is probable that the carnivora, by reason of their general habits and natural ferocity, are only more virulent in that they cause more severe wounds; but it is questionable whether this completely explains why the cat is so notably more dangerous than the dog.

The shortest possible incubation period has been determined by M. Pasteur's discoveries to be about seven days; this occurs most usually after subdural inoculation, *i.e.*, inoculation beneath the dura mater. The minimum period has, however, been clinically observed in children, but such cases are very rare. It occurs frequently in rodents after subdural inoculation, the virus having been perfected by transmission through several generations of such animals. The usual period of incubation after subdural inoculation is from fourteen to twenty-one days, and this period has often been observed clinically. The commonest incubation period in man, after subcutaneous infection by a bite or a scratch, is from six to eight weeks. The maximum is unfortunately undetermined, although there appear good grounds for believing that in very exceptional circumstances it may be as long as two years. Many of the cases in which the disease is stated to have lain dormant for longer periods have not been substantiated on complete investigation.

SYMPTOMS.—These for description are best grouped in three classes, corresponding with the stages of the disease:—(a) Premonitory; (b) Furious, or hyper-excitable; (c) Paralytic. Animals differ in the extent to which they exhibit each or all of the above classes of symptoms, but, if any case be carefully examined, each group is observable, though varying in degree and time.

(a) *Premonitory.*—The symptoms, especially in man, are hallucinations, a vague sense of fear and malaise, and frequently itching or irritation in the cicatrix. This may be excessive, and may amount to pain.

In this stage a man (or dog) behaves oddly and suspiciously. The appetite in the dog becomes depraved, and by the time the second stage is reached solid food is refused altogether. This symptom, although absent in man, is pathognomonic of the disease in the lower animals. The temperature begins to rise, the pulse and

respirations are accelerated, the voice becomes husky, and the bark and howl of the lower animal is characteristic.

	Stages.			Death by—
	Premonitory.	Furious.	Paralytic.	
Birds	...	well marked	well marked	syncope
Rodents	rare	rare	do.	coma
Ungulates and Ruminants	well marked	well marked	moderate	syncope
Carnivora	do.	do.	moderate*	syncope and coma
Apes and Man	do.	do.	rare	syncope

* The paralytic form is occasionally paramount in the carnivora, and the affection is then termed paralytic or dumb rabies.

Furious.—This stage begins with restlessness, causing the lower animal to break bounds and wander. Then follows hyperæsthesia, particularly noticeable in the ungulates and in man. Any afferent stimulus—*i.e.*, a sound, a draught of air, or the mere association of a verbal suggestion—will cause a violent reflex spasm. In man this symptom constitutes the most distressing feature of the malady. The spasms, which affect particularly the muscles of the pharynx and mouth, are exceedingly painful, and are accompanied by an intense sense of dyspnoea, even when the glottis is widely open or tracheotomy has been performed.

The spasm is usually brought on by the attempt to drink, and is then seen to consist in a violent elevation of the larynx and hyoid bone. The terror of re-exciting this painful spasm leads naturally to a dread of water, which has given the name to the disease in man.

Hydrophobia is, however, as already stated, a most regrettable term, and its use is to be deprecated since it encourages the popular delusion that so long as a dog drinks, or attempts to drink, it cannot be rabid, whereas it will gladly try to do so even in the last or paralytic stage.

The temperature in the "furious" stage reaches its maximum (in some cases 103°). During the paroxysms the pulse and respirations become quickened and irregular.

Paralytic.—Before the furious stage has ceased motor paralysis sets in, almost invariably attacking first the hind

limbs and ascending to the head, in a manner so exactly similar to that of "Landry's ascending paralysis" as to suggest that that disease may be only the completely paralytic form of rabies in man. As will be seen in the foregoing table, motor paralysis is the rule in rodents, and occurs occasionally in dogs, in which animals the condition of "dumb rabies" begins as a glosso-maxillary-laryngeal paralysis, and later attacks the hind limbs. In other animals it usually forms the final stage, and follows the furious condition.

As the paralysis spreads the temperature begins to decline and becomes subnormal, falling in the rabbit sometimes as low as 22° C. The respirations become slower and the pulse gradually weaker.

In this connection it is necessary to speak of the mode of death, which, owing to the frequently marked degree of impairment of the medulla, often occurs in man and the larger animals by sudden syncope. When the motor paralysis is a very early and prominent feature—*e.g.*, in rodents—death usually takes place by gradually increasing coma (*vide* Table, *supra*).

MORBID ANATOMY.—The morbid anatomy of rabies is very simple. Owing to the fact that the virus produces functional changes of great severity, but of short duration, if the animal dies or is killed in an early stage, but few lesions are found after death. As a rule, if the disease runs its full course, the post-mortem appearances are quite characteristic. The lesions are confined almost entirely to the central nervous system, the alimentary canal and the respiratory tract; the serous membranes remaining perfectly healthy; rigor mortis is well marked.

Nervous System.—The whole of the central nervous system is usually the seat of acute though moderate inflammation; sometimes, however, only patches here and there show any changes. The vessels are greatly congested, and, consequent upon the congestion, exudation of leucocytes takes place into the peri-vascular lymphatics; hæmorrhages also occur, but these may obviously be, in part, accounted for by the mode of death.

Alimentary Canal.—According as the disease has run a furious or paralytic course, the pharynx will be more or less congested, and either covered with sticky mucus or dry. The gullet is usually normal, but the stomach is, as a rule, markedly congested. In some animals—*e.g.*, rodents—hæmorrhages are almost constantly present in the mucous mem-

brane of this viscus. In any case the fluid contents of the stomach are usually coffee-ground in appearance, from the presence of altered blood. Owing to the depravity of the appetite at the onset of the disease, the stomach in the lower animals very frequently contains foreign bodies—*e.g.*, hay, pieces of wood, stone, &c.; but the presence or absence of these things is not alone pathognomonic. To the loss of appetite is due the fact that the rest of the alimentary canal is usually empty.

Respiratory System.—The larynx frequently participates in the congestion of the pharynx. The trachea and bronchi are often markedly congested. The lungs usually show some patches of acute broncho-pneumonia with hæmorrhages. More usually the lower lobes are collapsed and œdematous.

Circulatory System.—The heart is always normal; the blood is frequently to a large extent fluid, but contains dark-coloured post-mortem clots.

In the liver, spleen and kidneys, changes similar to those seen in the central nervous system have been described, but only rarely, and subdural inoculation from these viscera has produced no effect, thus showing that they contain practically none of the virus.

Finally, the bladder is distended, especially in the paralytic stage.

In cases where the macroscopic evidence and clinical history are alike doubtful, subdural inoculation affords a ready and certain test of the existence or absence of the disease.

TREATMENT.—This terrible disease can, and should, be prevented from existing in any given country where the following measures are possible:—(1) Proper muzzling of all dogs; (2) humane destruction of all ownerless dogs; (3) proper quarantine or other measure against the importation of the malady.

Where such regulations have been in force the disease has been completely eradicated in a few years.

If, unfortunately, owing to the supineness of the authorities, it be endemic, as in this country, treatment falls under the two heads of—(a) Treatment preventive of the evil effects of the bite; (b) Treatment directed towards the palliation of the painful symptoms when they have appeared.

(a) **Preventive Treatment.**—No preventive treatment is known to be successful except that devised by M. Pasteur. This consists in the subcutaneous injection on successive days of several cubic centi-

metres of an emulsion of the dried spinal cord of rabbits that have died from the most acute form of rabies.

In Pasteur's treatment chemical substances produced during the culture of an organism, and known to be inhibitory to its growth, are introduced into the system.

This treatment is unattended by danger or untoward results—*e.g.*, the production of abscess—and its adoption has reduced the mortality among those bitten by indubitably rabid dogs from 15 per cent. to 1.3 per cent. The value of this discovery cannot therefore be over-estimated.

(b) *Palliative Treatment.*—As soon as the first symptoms have declared themselves, the aim of palliative treatment should be—(1) to diminish as far as possible the production of reflex spasm or excitement; and (2) to sustain the strength of the patient.

(1) The patient must be placed in a darkened room, kept quiet and warm; all draughts must be excluded. He must be brought thoroughly under the influence of morphine, or rectal injections of bromide of potassium and chloral may be given, but, owing to the risk of inducing syncope, chloral is a dangerous drug to employ. The sensitiveness of the pharynx may be conveniently reduced by the local application of a 20 per cent. solution of cocaine. None of the vaunted specifics—*e.g.*, the hot-air bath and curare—are of the slightest service. The employment of any but powerfully narcotic drugs is as useless as it is cruel.

(2) Nourishment must be given to the patient by means of nutrient enemata and suppositories, to avoid the spasm in the throat caused by attempts to swallow. At the beginning of the paralytic stage the patient can often swallow a little fluid with great relief, and consequently an apparent improvement is thus obtained unhappily only of a temporary kind.

HYSTERICAL OR PSEUDO-HYDROPHOBIA.—Cases from time to time occur in which neurotic persons bitten by dogs, whether rabid or not, develop symptoms resembling rabies in some particulars, and such are often recorded as marvellous cures of the real disease by drugs. A differential diagnosis may be arrived at by observing the following salient points:—

Furious Stage.—In this stage the hysterical patient usually barks like a dog, and attempts to bite everybody, even himself. He can always be deceived by suggestion, and will thus at one moment

display reflex excitement and the absence of it the next, although the stimulus be adequate in each case. The patient speaks very much about the animal by which he was attacked, whilst in genuine cases this is very rare. The state of the temperature is the most valuable test, as hysterical hydrophobia is an apyrexial affection. The pulse and respiration show no marked quickening. Finally, the absence of true mental disturbance, the stationary character of the general symptoms and the concurrence of hemi-anæsthesia or other hysteroid symptoms all help to make the diagnosis of spurious rabies obvious.

Treatment.—The confidence of the patient should be gained, and then, by suggestion and moral suasion, a cure can easily be effected.

VICTOR HORSLEY.

HYDRONEPHROSIS.—A distension of the kidney by accumulated fluid, accompanied by atrophy of its substance, the result of some obstruction in the lower urinary passages.

Symptoms.—A hydronephrosis of moderate size causes a tumour to appear in the region of the kidney, which has the usual characters of a renal tumour, detailed elsewhere (*see KIDNEY, TUMOURS OF*). The special characters are its softness, the presence of well-marked fluctuation evidencing its cystic nature, occasionally slight mobility, sometimes a lobulated outline, and generally the absence of pain or tenderness. When both kidneys are affected, a tumour may appear on both sides of the abdomen, but is then rarely of large size. In some cases the tumour disappears, or diminishes in size, coincidentally with a sudden discharge of urine. This, when present, is a most important diagnostic sign. Further, such an occurrence may take place again and again, constituting an "intermittent" hydronephrosis. Pressure upon neighbouring organs by a very large cyst sometimes causes the only symptoms complained of by the patient. Obstruction of the intestines may thereby be produced. If one kidney only be attacked, and the hydronephrosis be too small to cause any intumescence in the abdomen, no symptoms or signs may be observed which can be directly connected with it.

Diagnosis.—The signs of a renal tumour sufficiently indicate how a hydronephrosis is to be distinguished from cysts arising in other parts. Fluctuation and the absence of hæmaturia and

pain differentiate it from malignant and other solid tumours of the kidney. Pus in the urine, at one time or other, with rigors and pyrexia, characterize a pyonephrosis, but hydronephrosis may pass into this condition. A history of symptoms of renal colic produced by gravel or the presence of some other cause of obstruction to the urinary passages, serve to distinguish hydronephrosis from other cysts of the kidney. The discharge of hydatid vesicles in the urine demonstrates the nature of a cyst of parasitic origin. A perinephritic abscess is more diffused than a hydronephrosis, it is not movable, is accompanied by pyrexia and redness of the skin, and is painful and tender. Finally, the intermittent appearance of a hydronephrosis, when this occurs, is a conclusive test of its character.

Pathology and Morbid Anatomy.—The cause of hydronephrosis is always an obstruction of the urinary passages. The obstruction may be actually in the passages themselves, such as a calculus blocking the ureter; it may be a contraction of the ureter from the cicatrization of an ulcer formed during the previous passage of a calculus along the tube; it may result from a growth of tubercle in the mucous membrane of the ureter; or, again, it may be due to pressure on the ureter by tumours of different organs, peritoneal bands, or inflammatory exudation following injury.

Congenital deformities are sometimes causes of hydronephrosis. Amongst these are to be mentioned absence of the ureter, imperforate ureter or urethra, contraction or twisting of the ureter, compression of the ureter by an abnormal artery, folds in the mucous membrane of the ureter, and the entrance of the ureter into the pelvis of the kidney by an oblique opening which closes in a valve-like manner. The movement downwards of a floating kidney may so fold the ureter as to obstruct the flow of urine along the tube, and consequently produce a hydronephrosis.

It has been suggested that frequent micturition, from whatever conditions arising, may cause hydronephrosis, by the compression which the contracting bladder exerts upon the ureters. Congenital hydronephrosis is often accompanied by other congenital deformities.

When obstruction to the free passage of urine from the kidney is established, the secretion accumulates in the pelvis of the kidney. First the pelvis, then the infundibula, becomes distended, and

this, provided that no inflammation of the pelvis be set up, constitutes the first stage of hydronephrosis. It has been found, experimentally, that there is at first congestion of the kidney, due to pressure on the veins contained in the pyramidal portion, and that this gives way shortly to anæmia from pressure on the arteries. The papillæ which project into the pelvis become compressed on all sides and soon atrophy; they have even been known to become necrotic, and to be thrown off *en masse* into the pelvis. The increasing pressure of retained urine soon causes atrophy of the whole of the pyramidal portion of the kidney. The cortical portion becomes indurated from an overgrowth of fibrous tissue, and finally, in extreme cases, undergoes pressure-atrophy, and, gradually wasting, may eventually disappear. Yet the fœtal lobulation of the kidney is often somewhat evidenced in the diseased structure. Shadowings of the lobulation are seen on the surface; in the interior, fibrous septa, running inwards from the periphery divide the cavity into several loculi, which communicate only through the pelvis.

Such a condition is a fully developed hydronephrosis, a loculated sac, having fibrous walls, in which islets of kidney substance are often imbedded and filled with a watery fluid containing urinary ingredients. But the type is subject to variations. There may be no loculi, but only a single cavity, or the loculi may be few and imperfect.

If the obstruction be situated in one ureter, only the corresponding kidney will be subject to hydronephrosis. But both ureters may be separately blocked, or they may both be involved at their terminations in one cancerous tumour, and then both kidneys become hydronephrotic. Moreover, not infrequently a kidney has two ureters and two pelves; one only of these may be blocked, and consequently only that portion of the kidney corresponding to the obstructed ureter becomes distended, the remaining portion carrying on its functions as before.

The size of the hydronephrotic sac is variable; it may be enormous, or, on the other hand, smaller than a normal kidney.

In the early stages the contents of a hydronephrotic sac are ordinary urine. But soon actual secretion becomes abolished, and the fluid is simply a transudation from the blood. It is then more watery than normal urine, but con-

tains urinary salts and extractive matters, together with a little albumen, cholesterol, fat, blood, epithelial elements, and small quantities of inflammatory products. Cases are recorded in which the cyst contained colloid material.

When hydronephrosis is unilateral, the opposite kidney becomes hypertrophied, and for a long period may satisfactorily supply the needs of the body. The heart becomes hypertrophied, especially in its left ventricular portion. Even when both kidneys are disabled it is sometimes remarkable how much atrophy of both organs may take place before life is destroyed. It must be noted that in most cases the obstruction which causes distension of the kidney is not total, or at least is so only for limited and broken periods. When total obstruction has taken place the pressure in the kidney will soon rise so high as to stop secretion and transudation, and therefore simple atrophy of the kidney is most likely to be the final result.

Results.—The distension may overcome the obstacle and may not recur, the kidney being left in a more or less disabled condition, according to the length of time the obstruction has existed. Pressure upon surrounding parts in time causes exhaustion, or occasionally more rapid death from intestinal obstruction. Rupture into the peritoneum is rare, but when it occurs is usually fatal. A double hydronephrosis eventually kills by the supervention of uræmia.

Occasionally the cyst suppurates, then producing a pyonephrosis. It must also be remembered that with one kidney disabled by hydronephrosis the impaction of a calculus or any other obstruction in the opposite ureter will cause fatal suppression of urine.

Prognosis.—The prognosis is always grave, but not so serious as in other renal tumours. If both kidneys are affected the prognosis is more serious than when one only is diseased. Yet life may be prolonged for a considerable period if the obstruction be incomplete.

Treatment.—The obstruction has been overcome by shampooing the swelling. When there is great distension this is inadmissible. If distress be experienced and serious mischief is threatened from pressure or rupture, the sac should be tapped. The best situation for the puncture, as determined by Mr. Henry Morris, is just anterior to the last intercostal space, if the tumour be on the left side, or halfway between the last rib and the crest of the ilium, from 2 inches to 2½

inches behind the anterior superior spine of the ilium, if the tumour be on the right side.

Incision is required if the cyst suppurate, or if, after aspiration, the cyst repeatedly refill and dangerous symptoms again arise. The incision is to be made in the lumbar region, and the cyst drained and irrigated antiseptically. Nephrectomy is a last resource when the useless remains of a kidney are causing exhausting suppuration. Rupture of the cyst into the peritoneum has been successfully treated by laparotomy and drainage.

ROBERT MAGUIRE.

HYDRORRHŒA GRAVIDARUM is a rare and curious disease, characterized by a discharge of watery fluid from the uterus during pregnancy.

Different opinions have been held as to the origin of the fluid.

(1) It is sometimes a discharge of fluid pent up between the decidua vera and reflexa, the fluid being produced by hypertrophied decidual glands; the disease, according to this view, being properly styled, "*endometritis deciduæ catarrhalis*." (2) It is believed to be due to rupture of the membranes high above the os uteri, and partial discharge of the liquor amnii. (3) It may arise from an excessive secretion by the glands of the cervix, analogous to the excessive salivation which sometimes occurs in pregnancy.

None of these theories are proved, though, in support of each, cases have been reported in which the facts rendered the explanation plausible.

As we have no accurate knowledge of the nature of the disease, no effective treatment can be described.

G. E. HERMAN.

HYPERTROPHY.—It is a matter of almost daily observation that the increased use of a part tends to enlarge and strengthen it; when enlargement from this cause is excessive, or results from some unusual condition of the corresponding or correlated organ, it is termed hypertrophy.

Parts are often described as hypertrophied when enlarged from other causes; it is desirable that the various kinds of enlargement be sharply separated from each other. The heart furnishes us with some typical forms.

At birth, the walls of the cardiac ventricles are of equal thickness in the human fœtus; on the establishment of pulmonary respiration, the work of the

ventricles is unequally divided, the left ventricle maintains the systemic, whereas the right ministers to the pulmonic circulation. In consequence of the greater amount of work required, the walls of the left ventricle enlarge, and are nearly three times thicker than those of the right. Such thickening is often called functional.

If at birth the ductus arteriosus should fail to obliterate, or the aorta arise in part from the two ventricles, the walls of the right ventricle will increase in size equally with the left: such enlargement is true hypertrophy.

Later in life the heart may exceed the normal size, in consequence of an accumulation of fat: such enlargement is pseudo-hypertrophy.

Functional enlargement of organs, consequent on increased use, is well illustrated by the uterus in pregnancy, the mammae in lactation, the testes of birds during the breeding season, the oviducts of fish, birds, frogs, and turtles, the muscles of the arms in boatmen and smiths, and the leg muscles in gymnasts.

As examples of hypertrophy, the following may be selected:—The thickening of the muscular coats of the urinary bladder in stricture of the urethra, vesical calculus, and, occasionally, in prostatic enlargement, but especially when an adenoma of the prostate produces valvular obstruction of the urethra; the muscular coats of the gall-bladder in old-standing cases of biliary calculi; the muscular tissue in the trachea and larger bronchi in individuals with chronic bronchitis; the walls of the small intestines above congenital stricture of the ileum, due to abnormal coalescence of the vitello-intestinal duct; and the walls of the œsophagus above a fibrous stricture. The muscular tissue in varicose veins becomes increased in quantity, due to the extra work required in supporting an abnormal quantity of blood. This condition may be most advantageously studied in varicose saphena veins, and in the pampiniform plexuses of young adults.

This marked tendency of plain muscle-fibre to hypertrophy may be turned to advantage in the operation of excision of the anus, for if only a small portion of the external sphincter be preserved, it will rapidly enlarge, and in a few months form an efficient valve, giving the individual absolute control over the outlet of the bowel.

The effects and advantages of increase in size and strength from excessive use

are well shown in the extra development of an arm or leg after its fellow has been amputated, especially in young and vigorous subjects. After amputation of the hallux at the tarso-metatarsal joint, the second toe will enlarge if the foot be used for walking, until it nearly rivals in size and appearance the lost toe. Probably all the tissues of the body respond in this way to increased use, even in the case of the testes. The museum of the Royal College of Surgeons contains a testis taken from a monorchis. Divested of the tunica vaginalis, it weighed 18 drachms and 2 scruples, was healthy in structure, and the epididymis was loaded with secretion. No testis could be detected on the opposite side. In cases of undescended testis, the retained organ is always abnormally small, whilst the descended testis is unusually heavy; this, of course, refers only to adults. The same applies to retained testis in monkeys.

The kidney furnishes some very striking examples of hypertrophy; when one kidney is slowly destroyed, its fellow, if healthy, will gradually increase until it doubles in size and weight. The secreting tissue of such kidneys is perfectly natural. Examples of single hypertrophied kidneys have been recorded often in man, in birds, sheep, oxen, and horses.

Under favourable conditions, bone will hypertrophy, although nearly all the specimens described in pathological museums as hypertrophy of bone are spurious examples of the process. Hypertrophy is occasionally exhibited by the fibula in cases of long-standing united fracture of the tibia; under such conditions, the fibula transmits the weight of the body to the ground—the increased use of the bone leads to its enlargement, thus enabling it to respond to the demand made upon it.

Hypertrophy of organs from increased use is inseparably connected with increased blood supply. The rapidity with which arteries enlarge is often quite marvellous. A study of this question in connection with the arteries supplying the growing antlers of deer was turned to practical advantage by Hunter in the treatment of aneurysm. A very similar change may be observed in the arteries of a limb when it is the seat of a sarcomatous growth. When amputation is performed at the hip-joint, in cases of large sarcomata connected with the lower end of the femur, the large size of those arteries, which in a normal limb are usually insignificant twigs, is very noticeable. In

man, the temporal arteries will hypertrophy rapidly after ligation of the common carotid artery of the opposite side, and become perceptibly larger in a few days.

It may be useful to enumerate some of the commoner forms of enlargement of organs frequently mistaken for hypertrophy, amongst which bone takes a leading position. Thickened bones in cases of osteitis deformans, mollities ossium, acromegaly, rickets and chronic periostitis or osteitis, cirrhotic and fatty livers, enlarged prostate, the brain in hydrocephalus, macroglossia, emphysematous lung, congenital enlargement of fingers, toes, or limbs, the thyroid body in goitre, inflamed testes and ovaries, and many similar conditions. Overgrown toe-nails, elongated beaks of birds, and teeth of rodents are often set forth as examples of hypertrophy; on the contrary, these owe their abnormal length to disease, not to increased use.

It has also been customary to regard the local thickenings of the skin on the hands and feet, known as callosities and corns, as examples of hypertrophy. A careful examination of the subject induces the writer to class them as thickening the result of irritation; according to this view they should be relegated to the class of pseudo-hypertrophies. That local irritation will induce thickening of a part is undeniable. The intermittent pressure of badly fitting boots will cause enlargement of the head of the first metatarsal bone; the irritation of the pre-patellar bursa, caused by frequent kneeling, as in housemaids, often leads to thickening of its walls until the cavity of the bursa becomes nearly filled with fibrous material. The callosities on the knuckles of the gorilla and over the sternum of camels are cases in point.

When the various forms of enlargement of parts are strictly analysed, we are forced to the conclusion that true hypertrophy is not very common.

In conclusion, a few remarks may be made on hypertrophy of the senses, for increased or abnormal use has a similar effect upon them as upon the tissues.

When an individual loses an eye by accident in early life, the remaining eye, if healthy, acquires a greater range of movement and quickness, which compensates in no small degree for the loss of its companion. In those born blind, or who lose the sense of vision in early life, the power of hearing becomes wonderfully acute and not rarely tactile sensibility becomes so intensified that

such persons make themselves acquainted with external surroundings in a marvellous manner.

The mole furnishes a good example of this form of hypertrophy, its auditory acuteness is proverbial. It is said that the blind fish of Kentucky are acutely sensitive to sound as well as to undulations of the water produced in various ways.

J. BLAND SUTTON.

HYPNOTISM.—A term of neutral colour introduced by James Braid, of Manchester, in 1843, to describe some symptoms, in many ways like natural sleep, which he had been able to induce in some men and animals by means, as he thought, of fixed attention.

Phenomena of the same class, and in many respects identical, had been forced on the attention of the Western world by Anthony Mesmer after he came to Paris in 1778, and had, along with some extravagances, been christened as "mesmerism" by an uncritical clique, and as "animal magnetism" by others who were not physicists. They had puzzled and interested some honest and learned *savants* and doctors in the earlier years of this century—De Puysegur, Pététin, Du Potet, Magendie, Esquirol; but an *à priori* prejudice against their reality was so strong that the French Academy of Medicine in 1833 refused to print the Report of its own commissioners upon them because in it they had admitted the truth of some of the experiments which the mesmerists had exhibited.

Dr. John Wilson in 1839 "mesmerized" elephants and wolves, and Braid, aroused by the lectures and demonstrations of Lafontaine, and starting from a position of hostile scepticism, clearly showed, to his own surprise, that not only animals, but also human beings, could be affected after this mesmeric fashion, and by the candid study of this "neurohypnology," or "hypnotism" as he afterwards called it, helped most materially to break down the popular suspicion of universal fraud in the matter, and further offered a physiological hypothesis of its causation by fixed attention.

Esdaile, a surgeon in the service of the East India Company, independently, in 1845, at Hooghly, before chloroform had been introduced into India, showed most conclusively that by hypnotism such complete anæsthesia could be produced that lithotomy, amputation above the knee, and many other major surgical operations could be performed, without the knowledge of the patients, during

hypnotic states lasting some ten or twelve hours.

The use of chloroform and ether for a time diverted attention from the anæsthetic conditions of hypnotism, and its abnormal psychical states were not seriously considered in the scientific world.

Azam and Broca pointed out their importance in 1860, and in 1866 Liébeault, of Nancy, published the results of some years of the use of hypnotism in medicine, which were for the time almost universally neglected. Charles Richet in 1875 demonstrated afresh the physiological facts, and threw new light upon them; many French physicians began to take an interest in them, and a few German physiologists. Charcot in 1878 began to make experiments which were confined to the hysterical patients in the Salpêtrière, and in 1882 Bernheim began a much wider trial of hypnotism on his patients with all varieties of disease in the large hospital of Nancy, where Liébeault's long experience had at last given his practice and beliefs great influence, and since then there has been rapid spread of experiment and knowledge through France (A. Voisin, Pitres, Grasset, Beaunis, Dumontpallier), Italy (Lombroso, Tamburini), Germany (Heidenhain, Preyer, Krafft-Ebing, Moll), Switzerland (Forel), Belgium (Delbœuf), Austria (Benedikt), Russia (Danilewsky), and Sweden (Wetterstrand); but to this the medical world of England has added very little.

A few words of retrospect have been necessary to show how scattered and probably incomplete the evidence is for any final generalizations in the very difficult problems of the psychical and physical conditions of hypnotism and its application to medicine. It would be out of place to recount the attempts at solution of these problems, mostly the results of a limited view and a desire for rapid systematization, or at least a working hypothesis. There is needed in the hypnotizers self-confidence, determination, and probably some personal quality not yet determinable; in the subject, at least to begin with, a passive acquiescence. The hypnotizable have no exact distinguishing marks; they are to be best found by trial; in greater numbers among the younger subjects and less educated classes; more frequently, probably, among the French and Italians than among the Germans and English; not to any marked extent more among women than men, among sick than healthy, or among

hysterical than non-hysterical persons, though some hysterics have been easily trained into more elaborate symptoms.

Hypnotism is occasionally induced for the first time by mere authoritative command or suggestion in those who know little or nothing about the expected state; more often by some description of the sleeping state that is to follow, accompanied either by long gazing at something fixed, best held near to, and above the level of, the eyes, so as to induce an upward convergent squint, or else by directing attention to some monotonous stimulus to eye or skin or ear, such as slow downward passes made by the operator's hands before the subject's eyes, or gentle uniform stroking of the forehead, or holding a ticking watch to the ear. Occasionally some parts of the body have been found abnormally sensitive—*e.g.*, the eyeballs or vertex—and pressure on them is followed by hypnotism (P. Richer, Dumontpallier). In all these cases the part played by expectation and suggestion cannot be eliminated or accurately estimated.

The common hypnotic physical results as seen in the healthy subject are that the eyelids close and he cannot open them, and that his eyeballs roll upwards into a position of slight characteristic convergent squint; there is generally increased excitability of muscle and peripheral nerve, with a lessening of the time of involuntary and increase of time of voluntary reflex (Stanley Hall), and some anæsthesia. Among the psychical phenomena there is a loss of spontaneity in his acts, and a ready obedience to commands, however ridiculous, and confident belief in any delusion, however absurd. The patient is, as a rule, alert and most impressionable, and in fact is ready to form the buffoon of the platform experimenter. In such a subject contraction or stiffening of a limb may be induced by light surface-friction and suggestion, and the arm, stiffened in extension, may be held out at right angles to the shoulder without tremor for even seven hours (Berger), whilst the same individual in a normal state will find it difficult to resist tremor after extension for some seven minutes, and collapse from exhaustion in a quarter of an hour. There may be also a cataleptic condition, following generally upon some shock of sound or sudden light, but in this the *flexibilitas cerea* is imperfect.

In a subject in such states as these some traces of memory often persist after awakening; a dim recollection, for ex-

ample, of feeling unable to refuse obedience to an order which was felt to be ridiculous or fancied to be impossible. His tendency, if nothing keep him alert or restore him to his normal condition, is to lapse into a deeper state, for which there is no more accurate border line than can be drawn by his complete absence of memory of what has happened in his deeper state, either on being completely wakened or on being roused so as to re-enter his previous more alert state (Gurney). But full memory of either alert or deep condition, and of that alone, recurs to him when that condition is re-induced, as in natural somnambulism the somnambulist forgets his ordinary life, but remembers his actions in previous somnambulant attacks. Throughout he is obedient to command, and so exceedingly susceptible to suggestion that he will act on it sometimes a year after he has been waked (Beaunis), though, if given when in a deeper stage, he will know nothing of this post-hypnotic suggestion until he enacts it, and then be quite unaware of the reason of his actions. In the deep state there is, as a rule, a tendency towards falling into a heavy sleep, which gradually becomes normal, and from which the subject wakes with little or no discomfort. Under some circumstances of disease, and more especially of psychical abnormality, such as hysteria, different types of conscious or unconscious suggestion from the hypnotist are very delicately appreciated by some hyperæsthetic subjects, and many variations occur. Stages of lethargy, catalepsy and somnambulism are described by Charcot as occurring in this sequence in his hysterical patients at the Salpêtrière, but are not found after the same pattern elsewhere, even in hysteria, by hypnotists who are not acquainted with them or do not expect them.

Turning to the uses of hypnotism in medical treatment, we find that they may be roughly divided into the relief of pain, the obtaining of sleep, and the large group of consequences or concomitants of the change of some functional activity or mental attitude under post-hypnotic suggestion. In such a case, for example, as that of a middle-aged man with severe double pneumonia, high fever, insomnia, and incipient delirium, hypnotism has been induced on first sight for the first time in about ten minutes by Bernheim, and, after a vigorous and repeated command to sleep, complete and refreshing sleep has followed for five hours in the middle

of the day, with very substantial benefit, and without the drawbacks generally attaching to hypnotic drugs in such a case. The relief of the most severe pain, such as that of acute articular rheumatism, locomotor ataxy, &c., has not been reached, but some sub-acute cases of articular rheumatism, and a few of chorea, obstinate sciatica, and many lesser inconveniences, have been entirely cured. After experiments on more than 8000 patients at Nancy, and many others at Toulon (Fontan, Ségard), at Montpellier (Grasset), at Bordeaux (Pitres), at Zürich (Forel), at Amsterdam (van Eeden), at Berlin (Moll), at Munich (Schrenck, Notzina), and elsewhere, the disposition is to continue and extend the treatment.

In surgical operations it has been rarely tried of late, as the administration of anæsthetics has improved and is much more universally applicable; still, there are several well-recorded recent instances of childbirth being rendered painless (Pritzl, Mesnet, Liébeault), and a few surgical operations also (Tillaux, Boursier).

The receptiveness to suggestion in the subject gives the main power to the hypnotizer, in the form of a suggestion or command to be carried out, it may be, a long time after awakening, and is thus applicable to the control of morbid impulses, such as a morphine or alcohol habit, or hysteria. A patient who is susceptible to this extent imagines his new post-hypnotic inclination to be his own self-engendered idea, and readily acts upon it. In many instances it has, after more or less frequent repetition, proved stronger than his original habit, and he has rejected with disgust what was formerly his chief pleasure.

In cases of acute and chronic insanity it has been, as a rule, difficult to gain the quiet acquiescence necessary at first, but it has been found possible, in several of the few cases where it has been tried, to overcome by patient hypnotism destructive and pernicious tendencies entirely for a time, and probably permanently, though the results are too recent to afford complete evidence (A. Voisin, Forel). The limits of the powers of post-hypnotic suggestion have not as yet been thoroughly investigated; it is possible that by hypnotism power may be put into the wrong hands, and, consequently, it is always desirable that it should be attempted only by the medical advisers or under strict medical supervision.

A. T. MYERS.

HYPOCHONDRIASIS.—The term originated in the ancient belief that the seat of the disease lay in the organs behind the xiphi-sternum and below the diaphragm. Although in the present day an abnormal cerebral condition is considered the source of the affection, the expression, nevertheless, sufficiently marks its most frequent causal relationship. It is very difficult to define with accuracy its exact limitation, for the disease is on the border-land of insanity, and many cases seem to partake of both a melancholic and hypochondriac element. In the present article the term will be restricted to cases of mental depression originating in morbid sensations.

Symptoms.—As a rule, some little derangement, probably of the digestive tract, occurs in an individual unduly anxious concerning his health. He has picked up some scraps of medical knowledge, and ascribes the symptoms to some serious disease. He now eagerly examines his tongue, pulse, urine and feces, and finds in most or all some corroboration of his fearful anticipations. Probably he consults popular medical text-books, adapts positive facts to his present condition, and unconsciously ignores conclusive negative ones, and this although he be gifted possibly with a superior intelligence. All his thoughts are fixed upon himself, and focussed especially upon the particular organ which is the source of his trouble. One doctor after another is consulted, and specifics and nostrums of all descriptions are tried for the cure of the fell disease. He may even be persuaded that this cannot possibly exist, and happier days seem dawning when he becomes aware of vague pains or slight deviations from the normal which plainly point to some serious but indefinite disease.

This condition of affairs is a much more difficult one to cope with than the preceding, for it means that, in place of presenting a definite object for attack, the patient will carry on a guerilla warfare, and no sooner be dislodged from one position than he will assume another. Fugitive burning pains and paræsthesiæ are common in the course of certain superficial nerves, and may also be referred to deeper tissues, such as the brain, heart, or lungs. These become the subject of great concern, and naturally develop and multiply under the attention bestowed upon them. The hypochondriac sometimes does not venture upon a diagnosis, but

is, nevertheless, firmly convinced that something is very seriously wrong somewhere. The symptoms which have so serious an import to him as a rule depend upon some functional disturbance, but it should be remembered that serious organic disease is occasionally present—e.g., cancer of the stomach or aneurysm.

In some cases sexual irregularities, by inducing in the mind of the patient a belief that he is becoming unmanned, cause a similar depression of spirits. In the same way as the hypochondriac whose troubles are of gastric origin, his entire attention becomes concentrated upon the erring organ; books, doctors, and quacks are consulted to no purpose, and he is fully persuaded that impotence is sure to follow. Such a conviction may so prey upon his mind that suicide may be attempted, but the hypochondriac is generally cager to live, and, though in a few cases he be tired of life, he is too great a coward to take it. Apart from questions concerning his health, his judgment is usually clear, and he suffers from no delusions or hallucinations. Sometimes, however, continual brooding over his bodily condition begets a belief of moral unworthiness, and that he is forsaken by God—opinions which at once introduce an element of insanity. The general condition of the hypochondriac is sometimes good and he looks in robust health, but frequently emaciation occurs, and his face wears an expression of anxiety and pre-occupation.

Diagnosis.—The only difficulty arises in determining if any grounds exist for the doubts and anxieties of the patient, for it must not be forgotten that in some cases actual organic disease is present, underlying the morbid mental depression. Hence an examination of greater care than usual is demanded in place of the superficial one which is often given in these cases. An ordinary hypochondriac misinterprets what is presented to his senses, but is not insane unless he develops delusions of unworthiness, &c., or takes an altogether unreasonable view of the case, as that his stomach is made of glass.

Prognosis.—This is never very hopeful, but is better in cases of recent origin, when there is no marked neurotic predisposition and the general vital condition of the patient is good.

Ætiology.—The most persistent forms of the affection occur in those who have a marked family history of insanity. In

others this may be absent, but some chronic derangement, probably of the stomach, has induced a condition of self-analysis which leads to the belief that the trouble is of serious organic origin. Hypochondriasis is essentially a disease of adult life and middle age. Men are more frequently its victims than women, and it is probable that many of the slighter forms occurring in the latter would be called hysteria.

Treatment.—It is an important element in the treatment of these cases that the physician gain the confidence of his patient by a careful review of his condition, and treat it as a real disease rather than as a product of the imagination. An endeavour should be made to relieve his self-concentration by recommending a course of travel, stimulating any interest he may before have felt in any particular hobby, and suggesting means, which will differ in each case, for his employment and the development of his sympathies and social instincts. Sea-bathing and exercise, especially horse exercise, short of that which causes actual weariness, should be also encouraged.

Medicinally, the treatment should be conducted on general principles. Derangements of the stomach, which are nearly always present, should be treated with appropriate drugs; flatulence, with creasote or sulpho-carbolate of soda; constipation, as far as possible with a careful attention to diet, and, failing this, with gentle aperients. Iron should be given in anemia, and Anstie strongly recommends cod-liver oil or other fats, even in cases in which there is no marked emaciation. The usual nervine tonics are not of much value in this condition.

WILLIAM GAY.

HYPODERMIC TREATMENT.

—The subcutaneous injection of a drug is the most speedy method of bringing a person under its influence. There are many reasons which at times render it undesirable or impossible to give a remedy by the mouth, but such contraindications do not affect its administration hypodermically.

All the alkaloids may be thus used, as well as many other drugs; ergot, for example, is frequently used hypodermically to check hæmorrhage. It should be remembered that drugs act more powerfully in this way, and a smaller dose must be used than would be given internally. Care should also be taken that the needle is sharp, and the syringe

should be scrupulously clean. The operator should be careful not to puncture a vein. In timid persons the spot to be punctured may be frozen with a mixture of ice and salt, or brushed with a 10 per cent. solution of cocaine ten minutes before the puncture is made, to obviate any pain.

Some care is necessary before commencing the use of morphine hypodermically in any case where pain is not obviously due to the presence of organic disease, especially in persons of nervous temperament, owing to the risk of inducing the "morphine habit."

HYPOGLOSSAL NERVE, Diseases of.—This is the motor nerve for the intrinsic muscles of the tongue, and also for all the extrinsic muscles, except the mylo-hyoid and digastric, but it does not supply—at any rate in the monkey—the sterno-hyoid, sterno-thyroid, and omo-hyoid muscles, which, in the monkey, obtain their motor supply through the descendens noni from the communicating branches of the first and second cervical nerves. Stimulation of the distal end of the divided hypoglossal of a monkey inside the skull is not followed by contraction of the depressors of the hyoid bone (see *Proc. Roy. Soc.*, vol. xlv., a paper by Mr. Horsley and the writer).

Two affections of the hypoglossal nerve are described—viz., paralysis and spasm. The former only is of importance.

Paralysis.—Like the facial, the hypoglossal nerve may be affected at its nucleus, outside the medulla, or in its course from the inside of the skull to the tongue. The movements of the tongue are also affected in lesions of the so-called motor cortex, and also of the motor fibres passing down from the cortex through the internal capsule and crus cerebri to the opposite hypoglossal nucleus. This form of paralysis of the tongue is discussed under the heading of HEMIPLEGIA (*q.v.*), and it may be remarked here that, whereas in lesions of one nucleus or one nerve, only the muscles of the corresponding half of the tongue are wasted and paralysed, in the case of the cortex or internal capsule some of the muscles of both sides of the tongue are paralysed for certain movements, but the muscles do not waste, and their electrical reactions are not altered, while, at the same time, there is usually some paralysis of the face and limbs of the same side.

Tumours in the substance of the medulla, or atrophy of the cells of, the

nucleus, as in bulbar paralysis (*q.v.*), will cause paralysis of the tongue. In the former case, the condition is associated with paralysis of the limbs of the opposite side; in the latter, the disease is usually bilateral, and is associated with atrophy and paralysis of the muscles of the lips, pharynx and larynx.

Outside the medulla, the hypoglossal nerve is liable to be compressed by tumours, syphilitic growths, or meningeal exudations, and it is particularly associated with lesions of the accessory nerve to the vagus, producing paralysis of the tongue, soft palate, and vocal cord of the same side. Caries of the upper cervical vertebrae may produce paralysis of the hypoglossal. Between the exit from the skull and the tongue the nerve is liable to be compressed by tumours in the neck.

In *paralysis of one half of the tongue* the muscular tissue atrophies, the mucous membrane is thrown into folds, and when protruded the tip goes towards the paralysed side. When resting in the mouth the tongue cannot be put over towards the paralysed side, and, if both sides be affected, it cannot be protruded beyond the teeth. In unilateral paralysis, speech and the power of swallowing are not much affected; but in *double paralysis*, pronunciation of the linguals and dentals is impossible, as this condition is most commonly associated with paralysis of the lips; all speech is lost, and, if the larynx be not involved, the patient can only phonate the vowels. Mastication and swallowing are also very difficult if the tongue cannot control the direction of the bolus of food. In bulbar paralysis, fibrillar tremors are observed. The electric reactions are altered when the nerve is involved, those of degeneration being obtained, while in bulbar paralysis, the muscles, as long as they exist, react to the faradic, but at the same time give the reaction of degeneration with the constant current.

Diagnosis of the seat of the lesion can usually be made by a careful examination of the extent of the paralysis and its association with other muscles. Bulbar paralysis is almost invariably bilateral, or soon becomes so. A unilateral paralysis, not associated with loss of power in the opposite arm and leg, usually signifies a lesion (often syphilitic) situated outside the medulla, and this is the more likely if it be associated with paralysis of the soft palate and vocal cord of the same side.

Prognosis is always unfavourable.

Treatment of unilateral paralysis should be anti-syphilitic, on the chance of that disease being the cause of the paralysis. Tonics and local treatment with the constant current, the positive pole being applied to the back of the neck, and the tongue gently stimulated by drawing the negative pole along it, and the administration of tonics, are measures to which a trial may be given. The treatment of bilateral paralysis is most commonly the same as that for bulbar paralysis (*q.v.*).

C. E. BEEVOR.

HYSTERIA and HYSTERO-EPILEPSY.—Hysteria, says one of its most patient students, never has been, and never will be, accurately defined; but we may say this much, that it is a state of functional disease of the nervous system with an almost unbounded variety of abnormal physiological symptoms, and with a strong tendency to the imitation of other diseases, and, further, that along with this there is associated some mental abnormality which is never purely intellectual, but at least in large part emotional.

It has a physiological as well as a psychological side, but it has no pathology that is distinctive; *i.e.*, it is associated with no known and constant abnormality of tissue.

The name arose from a genuine belief of the earlier Greeks, which originated before any study of pathology was attempted, that such states as this were due to shiftings and abnormalities of the uterus (*ὑστέρα*), and it is retained for historical convenience rather than descriptive accuracy, though the close interweaving in some cases of crises and impulses arising from the feminine reproductive system with various of the hysterical changes and abnormalities, is sometimes put forward as a lame *ex post facto* justification.

In about nineteen cases out of twenty the symptoms are found in women, and are rather more frequent in the decade between the ages of fifteen and twenty-five than in any other. The male cases, as a rule, are somewhat older. In a large minority of cases there is an inheritance of some nervous incapacity from the parents, not always of hysteria itself, but to a less extent of epilepsy, insanity, alcoholism, or of spasmodic neuroses, such as chorea, torticollis, and tic. All members, indeed, of the neurotic group of diseases have some relations with the arthritic family, so that we are not surprised now and then to see as close a connection between rheumatism and

hysteria as there is between rheumatism and insanity, and sometimes, also, between tuberculosis and hysteria.

Hysteria does not limit itself to one type of climate, or one family of races, though it is more at home among an educated people and a white-skinned race. The negroes, their observers in the United States tell us, have only had hysteria since emancipation (Hammond). It used to be a commonplace that it was the result of the cloister life of a religious sister; that fashion of life is less familiar now, and it is commoner to trace the hysterical symptoms as sequelæ from a life of indiscriminate indulgence. An excitable nature in exciting surroundings may reach a condition where a fit of hysterical convulsions may be determined by a trifling accident, emotional or physical, and a fright that is no more than a surprise, or a railway accident that is no more than the tremor of an express, may give rise to terrors that seem agonizing, or originate a hysterical hyperæsthesia that makes the spine too tender to be touched. If the results meet with sympathy, and the subject comes across others in whom similar symptoms have been more fully developed, some imitation is not likely to be avoided, and an epidemic may be started by neuromimesis which is practically baseless, but not fraudulent.

Bearing in mind, then, the mental substratum, of which more hereafter, we may look first at the other symptoms in more detail. Their mode of onset is commonly gradual. An impressionable, nervous child may grow up with constantly overwrought emotions—fits of crying, sobs, tremors, palpitations, headache, sickness, a fastidious appetite, and fancies that slowly declare themselves abnormal. In the adult, some discomfort of head or stomach may be gradually magnified till it becomes all-absorbing, and perverts a natural habit of life, though, possibly, in only one or two particulars. Much more rarely the first easily recognizable symptom is a fit of convulsions which is the outburst of a slowly gathering tendency.

The most radical division of the bodily symptoms is into the paroxysmal symptoms and the non-paroxysmal and inter-paroxysmal. (A) The **paroxysmal symptoms** do not, in England, decidedly present themselves in more than about half the cases where there is some clear evidence of hysteria. Their immediate origin may be in strong emotion or after long fatigue and strain; but if, as is so often the case,

successive attacks have broken down the self-control, a trifle may be sufficient cause, so that to any one unacquainted with the previous history and tendency of the patient they may seem spontaneous. The patient will often describe the ordinary or minor paroxysm, in the subsequent days when she has recovered a more settled equilibrium, as beginning with a feeling that is essentially anomalous, like many of the forms of aura in epilepsy, something that alters the plane of consciousness, and is, perhaps, accompanied by a sense of constriction at the waist, or weight on the epigastrium, or pain starting from the hypogastric region, and blending itself quickly with the sensation of *globus*, rising like a ball in the throat, and causing an ever-increasing choking, which can only be relieved by screaming and sobbing, and universal convulsions more or less violent that have some traces of purposive method, and no constant mode of progress.

These are generally attended by an incomplete unconsciousness and some regard to self-preservation, so that the patient, though perhaps tossing herself about violently and falling heavily without an obvious guard, yet by a subconscious wisdom avoids the fire, and does herself no very serious harm. Such a paroxysm ends gradually after the screaming has subdued itself into mutterings and moans, tears and sobs, or else, after a quiet time, as of syncope with an occasional sigh, by a slow return to complete consciousness, and a more or less incomplete memory.

There is a wide range of variety in such scenes, and the individual character and habits of the patient may make themselves felt in many ways. Many are very short and trivial. An impression of the internal predominance of a separate power of evil or good, which overpowers the actions and the will, is one of the more serious interpretations of this sudden loss of self-control, and may lead to the terror or horror of what has been widely known as "possession," with its attendant struggles and hallucinations of a morbidly active imagination. Or, if there be less discomfort and more self-confidence, it may result in a temporary exaltation, or even ecstasy, in which the limits of the possible or the material seem easy to overstep. Again, in the weak and anæmic subject the attack may have more of the character of a fainting-fit, especially if there be some undercurrent of secret emotion that leads to exhaustion. In some of the severer

cases a comatose state may supervene, which has to a superficial observer the look of apparent death, but in which some tremor of the eyelids, and remaining sensibility of the conjunctiva and iris, as well as the persistence of the circulation, as shown by the results of deep puncture of the muscles, if not by the heart sounds or pulse, furnish sufficient grounds for a diagnosis.

Hystero-Epilepsy.—There is a group of severe and elaborate cases which has become stereotyped in the judgment of some French observers of the school of the Salpêtrière, as having an ideally complete course of prodromata, aura, and four periods of paroxysm—the epileptiform period, the period of *clownisme* (Charcot) or contortion, that of emotional attitude and gesture, and that of delirium. To a long display comprising these or the greater part of these symptoms, the name of *Hystero-epilepsy* or *Hysteria major* has been given. This is of use as a short term for a complex whole, so long as it is remembered that it is not intended to connote epilepsy in hysterical dress, or epilepsy complicated with hysteria, but only hysteria with some imitation of epileptic symptoms. Any attainment of the complete type, except in the Salpêtrière school, is very uncommon, but various portions in varying intensities are more widely seen.

The prodromata on the psychical side are marked, as in other hysterical cases, by neglect of the minor duties of life, foolish carelessness, excitable perversity, and perhaps some pleasure in grumbling; and on the physiological side there are likely to be some perversions of taste or sensation, some dyspeptic symptoms of nausea or tympanites, some polyuria or ptialism, and some muscular tremor or paresis.

In such a state there is frequently peculiar sensitiveness of some limited parts of the body, where a light touch may excite convulsions, and in some cases a deeper pressure control them. These "hystero-genic" spots are generally bilateral and symmetrical, and most commonly in the hypogastric, iliac, or submammary regions, but sometimes in the nerve trunks (Pitres and Gaube) or elsewhere.

The first period of convulsion is the most epileptiform, of less abrupt onset and longer duration than true epilepsy, without the epileptic cry; beginning perhaps with grinding of the teeth, and going on to some tetanus, with cyanosis,

marked opisthotonos and spasms of the arms in flexion, and legs in extension, repeated several times, and followed by a more clonic state of oscillating spasm of arm, or leg or body, which resolves itself gradually, after some foaming at the mouth, into a condition of relaxed muscle, and possibly stertor. If the complete course be pursued, after three or four minutes (P. Richer) of the epileptiform state, a period of miscellaneous contortions follows in which there is probably some beginning of the return of consciousness, and this is succeeded by a series of displays of emotion and plastic cataleptic poses, and that again by a confused delirium of recollections and illusions, which may last several hours or more, but gradually gives way to an inter-paroxysmal condition in which the functions may be completely normal, or on which the paroxysm may have left some trace in the form of the acquisition or disappearance of a contraction, a paralysis, or a mental perversity.

That any such exact sequence or tabulated form of symptoms should be systematized into a complete type of the malady of which all other manifestations are incomplete reproductions (P. Richer) implies a theory of disease which needs confirmation, and its occurrence chiefly among groups of patients where imitation is possible must be considered along with the quick susceptibility of a morbid class, such as the hysterics, to mould themselves to what is expected of them, and to become amenable to suggestions more or less unintentional and unconscious.

The resemblance to epilepsy does not go on to the extent of producing a *status epilepticus* with a high temperature and dangerous to life, though in a few rare cases the epileptic symptoms occur of bitten tongue, and, after the convulsion, of pupils almost insensitive to light; and indeed there is nothing to forbid the possibility of epilepsy concurring in the same patient as hysteria. The term *hystero-epilepsy* was more loosely used in the last generation, and is still sometimes applied to cases in which the symptoms of a simple attack by themselves were inadequate to establish a diagnosis without further knowledge of the antecedents, consequences, and concomitant habits.

(B) **Non-paroxysmal Symptoms.**—The symptoms which do not play a part in the paroxysmal attacks are of most Protean variety, and may pervert

nearly every function of the body towards excess or defect.

(1) *Motion*.—The group which borders most closely on the paroxysmal is that which includes some involuntary movements.

The *globus hystericus*, which the subject feels as some sudden obstruction rising in the throat, is due to an upward wave of muscular contraction in the œsophagus, and a spasm of the constrictor muscles of the larynx, and not unfrequently similar contraction may originate in the stomach, and produce sickness on very trifling or imperceptible irritation, and the impulse of regurgitation may spread so far down the bowel as to cause vomiting of most unusual matters, possibly even enemata (Briquet, Grasset) so as to satisfy the morbid desire of the patient for what may seem unprecedented. In a few cases in which the vomiting immediately follows swallowing, it has been well proved that the œsophageal muscles have thrown up the food before it has reached the stomach (Bristowe). Again, there may be many local troubles: the voice may be wholly lost, or more frequently there may be obstinate refusal to raise it above a whisper, or an imitation of the cries of animals may be resolutely adopted instead of human speech. The frequent hiccough, or *asthma uteri* of the ancients, the almost purposeless fits of laughing and crying, the irregular attacks of dyspœa, the anxious feeling of laboured cardiac palpitation, with some irregularities of rhythm, are some of the commoner symptoms which are often adopted as diagnostic, and so, too, is the hard, frequent cough that is a habit, and spasm without catarrh. There is rarely urethral spasm leading to some suppression of water (*ischuria hystérica*), and still more rarely a curious type of chorea, with regular rhythmical spasms for long periods, sometimes flapping of the hands, sometimes bowing of the body.

Of the motor symptoms, after the attacks are over, the *contractures* by tonic muscular spasm are not unfrequent, the apparent paralysis commoner and more inconvenient. The contractures generally affect one limb only, and are never accompanied by the organic hemiplegic affections of the facial muscles. There is most often flexion of the elbow or wrist, and extension of the knee or ankle, and many varieties of posture may supervene. The position and pain of disease of the hip-joint

may be very closely copied without any fraudulent intent, and examination under an anæsthetic may be often necessary before a satisfactory diagnosis can be made. Pain in such joints rarely prevents sleep, but recurs on waking, and spreads over a wide area, and one less intimately connected with the nerves of the joint than organic disease. The relaxation of the abdominal aorta, with the in-gathering of some of the muscles round it, may produce symptoms somewhat like those of a true abdominal aneurysm. But it is very variable, generally abnormally tender to manipulation of the surface even, and may be best investigated under an anæsthetic.

The condition of hysterical *muscular paralysis* is one that, in varying degrees, is very often seen, and one whose exact limits it is sometimes impossible to define. Its onset may be spontaneous, or it may follow a fit or emotional crisis; as a rule, it is accompanied by anæsthesia, without alteration of the electrical reactions of the muscles, and affecting the limbs from joint to joint rather than over the more elaborate distribution consequent on the initial injury of a nerve centre or nerve trunk. There is often aphonia, a condition common for a moment in normal vivid emotion, which may be indefinitely prolonged either absolutely, or as a whisper, for many months possibly. Its rapid onset and rapid cure, combined with the free motion of the vocal cords under the laryngoscope, are its best diagnostics.

(2) *Sensation*.—In sensation there is almost always some change from the normal, either increase, decrease, or perversion. The partial anæsthesia of the skin is one of the most frequent symptoms, though it may not be noticed by the patient, and may be so variously localized that it is difficult to find, especially if, as is sometimes the case, it be interspersed with hyperæsthetic patches. Its commonest distribution is over one limb or one side of the body. The want of sensitiveness to pain, to heat, to touch, to electrical changes, to contact (alphagesia, Pitres), do not vary concomitantly, as a rule. The anæsthesia often extends to the mucous membrane of the pharynx, nostrils, and vagina; less often to the conjunctiva, meatus auditorius, and membrana tympani. Hyperæsthesia of the breasts is common, of the genitalia occasional. In the extreme tenderness generally attributed to the ovaries, it is hard to say whether myalgia plays a part. A joint may be exceedingly sensi-

tive, and at first sight resemble organic disease, but it is characterized by being as tender in the skin as in the deeper parts (Brodie). Many of the miseries of neuralgia belong to this morbid class.

The *special senses* are also affected. There is sometimes amaurosis after sudden light, sometimes amblyopia; in the more advanced cases some achromatopsia. The experience hitherto has been that the discrimination of violet and green has been lost earliest, and that of blue and red retained longest. There is often retraction of the field of vision, rarely central scotoma or hemiopia. The sense of taste is more often blunted or lost, of hearing made more acute. In such a condition there is occasionally hallucination, in some cases visual, in more auditory, of a more fanciful nature than the rarer hallucinations of normal mental and physical life. The most complete investigations that have been made at present show very little, if any, greater susceptibility to hypnotism in hysterical cases than in normal subjects of similar age, race, and education (Bernheim, Grasset).

(3) *Circulation, Secretion.*—The instability of the vaso-motor system is a noteworthy point, and leads not only to rapid blushing and pallor, but in a few rare cases to subcutaneous hæmorrhage, hæmoptysis, and hæmatemesis, for which no explanation by fraudulent action has been thought adequate, though there can be no doubt there has been persistent deception in many cases. The secretions, too, have been affected. The rapid secretion of almost colourless urine after a paroxysm is one of the most constant symptoms; the long continuance of almost complete suppression of urine is sometimes simulated, and is in rare cases genuine (Charcot). Vomiting is a very frequent annoyance, and may proceed to such an extent as to become one of the most dangerous accidents, especially when complicated with obstinate constipation. Pyrexia and, occasionally, hyperpyrexia occur for which no organic or fraudulent origin can be found, and which may the more reasonably be considered to depend possibly on a morbid nervous condition in proportion as the evidence of hyperpyrexia, dependent on organic cerebral or spinal injury, gathers strength (Traube, Billroth, Ch. Richet). General nutrition is, as a rule, good in hysteria, compared with the diseases which it simulates, and practised observers have reported as much as ten

days' abstinence from any nutrition without serious injury (Brudenell Carter).

(C) *Psychology.*—The mental condition is one of the most variable and the most obscure of the constituents of hysteria. It is one of the essentials of the malady that the mind is not in all respects normal. There may be at first sight a condition of apparent equilibrium, stability, and good judgment which has some unconscious weak point in it, or which may be deliberately assumed to cover some morbid deceit conceived probably from an emotional cause. The desire to attract attention or to gain sympathy is one of the morbid habits of most far-reaching consequences, and may seek to attain its ends by making its victims show themselves martyrs not only in word, but in deed. They may scald themselves, blister themselves, wound themselves under circumstances when such anæsthesia as they have does not cover the pain, but where the obvious injury may do something towards gaining pity and sympathy. The absolute abandonment of truthfulness in persons of previously high character is striking, and sometimes hard for the friend or lay critic to believe. It is a point of morbid psychology not to be judged by normal standards. In some of the paralytic and lethargic states it has been very truly said of the mental side of their inertia that it is not that they cannot or they will not, but that they cannot will.

(D) *Diagnosis.*—Amid such a mass of functional symptoms in subjects avowedly imitative it is not to be wondered at that some cases of confusion with organic disease occur, and the occasional concurrence of hysteria with other diseases makes its exact limits impossible to determine. In the diagnosis from epilepsy in a single attack there may be insufficient evidence; the most important is the absence of the initial sharp cry, the more gradual onset of the paroxysm, its connection with surrounding emotional conditions, the absence of the signs of complete unconsciousness in action, and the absence of the post-epileptic insensibility of the iris. Of positive signs of hysteria we are gaining more confidence in the abnormalities of sensation such as are found by practised observers in as many as 93 per cent. of cases (Berbez). The retraction of the visual field, the segmental or patchy anæsthesia, most amenable to test observations when affecting the larynx, are some of the more important points. The untrustworthiness of the patient's word, and their

readiness to adopt any suggestion, render it necessary to seek evidence of which the bearing is to them obscure. Among the motor symptoms, a hemiplegia entirely without initial facial paralysis, a monoplegia without ascertainable local origin, a contracture coming on in sleep or in a few hours without antecedent paralysis, and the complete resolution of the contracture or disappearance of the paralysis under hypnotism or chloroform, is strongly confirmatory. At the same time, it is at least conceivable, though perhaps at present beyond strict proof, that what has begun as functional may go on to be organic; that a truly hysterical contracture may slowly turn into a sclerosis of the pyramidal tract (Charcot). That the mental condition of hysteria should have no hard-and-fast line to distinguish it from insanity, is in accordance with the boundaries of insanity on all sides, and for the hysterical patient to overstep the conventional line is not at all infrequent.

(E) **Prognosis.**—That anything truly hysterical will not be fatal is practically certain, but the length of duration of the symptoms and their severity depends in part on the individual constitution, and in no small part also on the firmness, tact, and patience with which they are treated.

(F) **Treatment.**—There is something to be done by prophylaxis in the children of neurotic parents; the nutrition needs attention, and strengthening by an extra amount of fresh air and exercise; the adverse possibilities of over-work must be avoided, and any chances of the difficulties of over-attention, luxury, and unrestrained wilfulness duly combated. When the malady has declared itself, and some of the symptoms are before us, we have more definite indications for treatment. If the patient be first seen in a paroxysm, and the disease found to be uncomplicated, there is perhaps a greater claim for neglect than for attention; a middle course may be in some ways convenient, but is none the less inappropriate.

If the patient be freed from all restraint, and left alone in a bare room till the fit is over, she will present her-

self, after a time, naturally recovered, and the probability of the recurrence of such an attack is materially lessened. But such treatment, to be successful, must be firm, based on a good diagnosis, and well supported by the friends and attendants in taking no notice of the symptoms between the attacks, and affording the patient no sympathy. It is rare that such a treatment can be carried out in family surroundings, and methods of strict isolation have met with much success, especially when malnutrition was part of the malady, and could be met and overcome by massage and a strict regimen of plain but abundant diet (Weir Mitchell). A careful treatment by hypnotism is beginning to claim some attention, for though by no means all hysterics are hypnotisable, yet in a fair proportion a hypnotic state can be induced in which post-hypnotic suggestions of the giving up of hysterical fancies, and the real extension of self-control, will be received and acted upon (Moll, Liégeois, Charcot, Grasset). If it be decided to give immediate attention to the attack, and treat it by active measures, a sudden and disagreeable shock by a strong electric discharge or bucketful of cold water may be effectual in stopping it, and sometimes violent pressure on the iliac region is found to have special efficacy, possibly as affecting the ovary. Chloroform and amyl nitrite are dangerous.

For the more chronic symptoms the administration of very offensive medicines, such as assafœtida, castoreum, &c., has no solid foundation, and is being gradually given up. A treatment by potassium bromide has little or no effect, and is very notably different to its action in epilepsy. Electricity and magnetism have no special virtue except as inducing passive exercise, which is useful in paralysis, and, if necessary, giving a sufficient shock, both mental and physical, to dissipate some paralyses or hallucinations. A careful and firm hand in keeping up a strict regimen and good digestion is very important; and, whilst undue attention is avoided, some of the emotional causes may be discovered and rectified.

A. T. MYERS.

I

ICHTHYOSIS (Fish-skin disease) is a congenital condition in which the skin is dry, rough, scaly, and covered with thick plates or wart-like growths.

I. Ichthyosis simplex is the commoner form of the disease, to the milder cases of which the term "Xeroderma" has, somewhat unnecessarily, been applied.

In such cases the skin is merely dirty-looking, dry, harsh, with constant furfureous desquamation and exaggeration of its natural lines and furrows. In severer cases large, thin, pearly, angular squames or thick plates are formed, which are separated by deep fissures or rifts corresponding in direction to the natural lines of the part; they are usually of a dirty grey colour, but may acquire a deep brown or greenish tint from decomposition of sebum and the accumulation of dirt upon them. The plates are adherent at the centre, detached at the circumference, and can usually be separated from the subjacent skin without causing bleeding. The appearance caused by these conditions to some extent resembles that of the skin of a fish or reptile.

Ichthyosis generally attains its maximum of intensity over the tips of the elbows and knees, above the ankles, and over the backs of the thighs and shoulders; it is seldom well marked on the scalp and face, and least of all in the flexures of the elbows, axillæ, knees and groins. The palms and soles are generally moderately affected, but in exceptional cases they may be the only parts attacked (*Ichthyosis palmaris et plantaris*: see CORN and CALLOSITY). The hair is scanty, lustreless and dry, the nails brittle, the lobes of the ears sometimes badly developed. In many cases there is heaping up of sebum and epithelium round the orifices of the hair follicles, especially upon the extensor surfaces of the arms and legs, producing a condition identical with *keratosis pilaris* in appearance; in many mild cases this often constitutes the most prominent feature (*I. follicularis*).

Sweating only occurs from the less ichthyotic portions of skin; it may be especially abundant in summer. The sweating softens and removes the scales and affords great gratification to the patient; but the advent of winter always

brings about an aggravation of the condition. Beyond slight itching, subjective symptoms are seldom complained of; but the skin being very vulnerable, troublesome dermatitis is of very frequent occurrence, especially upon exposed parts (*e.g.*, the face), and may mask the true nature of the disease.

Pathology.—Ichthyosis must be looked upon as a deformity rather than as a disease, the pathological changes consisting in abnormal thickness of the horny layer of the epidermis, and enlargement of the rete mucosum and papillæ, the vessels of which are dilated. The sebaceous glands are deficient in number and poorly developed, but the sweat glands are normal.

Ætiology.—Ichthyosis is sometimes hereditary and frequently affects several members of the same family. Although probably always present at birth it does not generally attract attention before the second or third year of life, as frequent washing is temporarily beneficial; at puberty the disease may either diminish or become intensified to a marked degree.

The condition known as "Harlequin fœtus" exemplifies the most exaggerated form of ichthyosis; it begins during intra-uterine life, and its subjects are always born prematurely, and have no external ears, eyelids or lips. One case has been known to live nine days.

"Ichthyosis linguae" is an unfortunate name used to designate a condition in no sense related to true ichthyosis.

Ichthyosis has been known to disappear completely after the exanthemata; it must be differentiated from *psoriasis universalis*, *eczema*, *dermatitis exfoliativa* and *seborrhœa tabescentium*.

Treatment, if diligently followed, is usually of signal, albeit temporary service. Frequent frictions with soft soap, followed by warm alkaline or bran baths remove the scales. The subsequent inunction of vaselin, oils or greases, glycerin or glycerin of starch, or a 5 per cent. naphthol ointment tend to keep the skin smooth and supple. Internal remedies are of little or no use, but *jaborandi* or *pilocarpine* might receive further trial.

II. Ichthyosis hystrix (*Hystricismus*) is a much rarer disease than the preced-

ing, and by no means closely allied to it, although the two have been said to co-exist.

The lesions are warty-looking growths consisting of elongated and hypertrophied papillae covered by greatly thickened, dark brown, horny epidermis, and forming flat-topped or pointed, spinous projections. These are grouped together to form patches, often unilateral, and distributed along the course of cutaneous nerves like zoster—*i.e.*, transversely on the trunk, longitudinally on the limbs. They are seldom present on the face, and if bilateral are never symmetrical. When situated on exposed parts, as the hands—where they are common—the horny caps are liable to be pulled off; in these circumstances only are they the cause of pain or other subjective symptoms.

They may be mistaken for warts or naevi.

Treatment is of service in mild cases in which the lesions are strictly localised. Scales may be removed by repeated warm alkaline baths with soft soap; or by soaking with a dilute solution of liquor potassæ. Concentrated solutions of salicylic acid in collodion or alcohol may then be painted on. Sometimes patches are best removed by scraping.

J. J. PRINGLE.

IDIOCY.—Idiocy is a defective development of the mental powers, dating from birth or early childhood. Imbecility is a minor degree of mental deficiency.

Symptoms.—The symptoms are physical as well as mental. The most important of the former are a general coarseness of the features and a lack of expression, thick and often everted lips, and a large, coarsely papulated tongue. The teeth are irregular, from delayed or abortive dentition and caries; the gums are swollen, and there is constant slavering, often with an offensive smell. The palatal arch is high and its development is asymmetrical; mastication is defective and often disgusting. The gait is waddling or staggering, and various paralyses and contractures of the limbs may be present. The powers of nutrition are imperfect; and the extremities cold and livid. One or more of the special senses may be absent or deficient. There is frequently strabismus. Mentally, the lowest class of idiots are organisms more helpless than the mindless plant, and in the best classes there is considerable weakness of the powers of attention, comparison, judgment, memory, fore-

sight and volition, and either complete absence, or only a slight development of the faculty of speech.

Idiots are very prone to learn bad habits, and to become mischievous and destructive, and are subject to attacks of mania or melancholia. Epilepsy, which is one of the chief factors in the production of idiocy, may also develop in an idiot. Masturbation is a common symptom and most difficult to check. When paralyses are present, choreiform movements and double athetosis are common. Stammering is also a common feature.

Varieties.—The following are the varieties usually described:—(1) Genetous, (2) Microcephalic, (3) Eclampsic, (4) Epileptic, (5) Hydrocephalic, (6) Paralytic, (7) Cretinism, (8) Traumatic, (9) Inflammatory, (10) Idiocy of deprivation.

(1) *Genetous Idiocy.*—The name is unfortunate, but is used to include cases in which, although the causation is indefinite, the condition dates from foetal life. Neurotic inheritance is the chief factor in the majority of such cases. The prognosis is fair when the physique is good, when there is some power of attention and some power of speech is shown by the time the child reaches the age of six years.

(2) *Microcephalic Idiocy.*—The chief point to be noticed is the smallness of the head. It is probable that a circumference less than eighteen inches implies idiocy. In these cases it is more likely that the skull ossifies over a brain which has ceased to develop, than that the growth of the brain is arrested by premature ossification of the skull. Microcephalic idiots are active and full of life, and improve greatly under proper training.

(3) *Eclampsic Idiocy.*—It is said that fourteen per cent. of cases of idiocy are due to infantile convulsions, but in the great majority of cases convulsions in infancy do not end in idiocy. Convulsions probably act as a predisposing cause to idiocy in a brain which is hereditarily weak, and are themselves a symptom of that weakness. Infantile convulsions are extremely common in the offspring of the insane. Idiots of this class do not admit of much improvement by training.

(4) *Epileptic Idiocy.*—In the eclampsic variety the fits are the starting-point of disease, but soon cease, while in the epileptic class the fits are both the starting-point of the disease, and a prominent feature throughout life. Epilepsy in

adults has a strong tendency to cause weak-mindedness, and on the developing brain of early childhood its influence is most fatal. Epilepsy developing before the seventh year will cause idiocy, but epilepsy may develop at any period when idiocy is established. These cases, like adult epileptics, are most troublesome, they are irritable, impulsive and pugnacious, but it is generally considered that the prognosis is as favourable as in other classes of idiocy, if not more so, and much may be done for them by proper training. The diet should include but little meat.

(5) *Hydrocephalic Idiocy*.—Hydrocephalus may develop either before or after birth. Generally it appears before the age of six months. It may terminate in weak-mindedness, or have but little effect upon the mental powers. The head is globular, widest in the frontal region, and sometimes flattened in the occipital region. There is usually deficiency of one or more of the special senses, and the limbs are puny. The aetiology of the disease is most indefinite, but tubercle, rickets, serofula, and hydrocephalus seem to flourish together in degenerating families. As regards prognosis, if the hydrocephalus be stationary and convulsions do not supervene, great improvement may be expected under proper training. Nourishing diet, cod-liver oil and iron are the main indications in treatment.

(6) *Paralytic Idiocy*.—Paralyses may exist from birth without causing idiocy, but some arrest of mental development is the rule. One or more limbs cease to grow and become atrophied and contracted. The paralyses are due to brain lesions caused by injury either before or after birth, or the result of inflammation, abnormal growths, or rarely hæmorrhage. Some mental power may be developed, but the physical condition admits of little amelioration.

(7) *Cretinism*.—This condition is fully described in the articles on CRETINISM, ENDEMIC and SPORADIC (*q.v.*).

(8) *Traumatic Idiocy*.—This class comprises cases in which the head has been injured during attempts at abortion or in delivery, or during early childhood. There may be distinct damage to the brain, or merely shock, and the degree of mental deficiency varies much, and bears little relation to the amount of apparent injury. Heredity unquestionably renders the brain more liable to suffer in this way.

(9) *Inflammatory Idiocy*.—The cases

described under this head belong usually to the last class. A few cases are said to result from the inflammation of the internal ear which is an occasional sequela of the specific fevers, but this is doubtful.

(10) *Idiocy of Deprivation*.—As the development of mental power is dependent upon that of the senses which bring the organism into relation with its environment, the deprivation of two or more of these senses must cause mental deficiency. The early training of the existing senses is the only treatment, and the case of Laura Bridgman shows how much can be effected in this direction.

Ætiology.—There are two males to one female idiot, and this is attributed with some reason to the larger size of the male head at birth. The premature closure of the fontanelles, and the small size of the frontal bone, must be regarded as the effect rather than the cause of the cessation of brain development.

In this, as in all forms of insanity, heredity is the great factor, 50 per cent. of the cases being demonstrably due to this cause. The inheritance passes most readily to children of the same sex as the affected parent. With heredity must be considered the other causes of the mental and physical degeneracy of families, among which the following are the most important.

The influence of drink is unquestionably most potent for evil, and is transmissible, and culminates in neurotic developments, but the statement that a drunken condition of the father at the moment of procreation will result in the idiocy of the offspring is most improbable. Idiocy is common among the children of aged parents, and among families in which tubercle and serofula are present. The consanguinity of parents and the existence of hereditary syphilis have but little ascertained influence in the causation of idiocy. In cretinism we have a general condition which has already been discussed, and finally some cases of idiocy are sporadic, and are considered as examples of reversion. Idiocy due to deprivation of the senses has been already described as a special variety. In this connection it may be mentioned that certain ethnological types have been discovered among idiots, and that examples of Ethiopian, Malayan, Mongolian, and other types have been described. These cases are most interesting from the point of view of the evolutionist.

The connection of chronic criminality and idiocy is probably intimate but has not been clearly proved.

Treatment.—In idiocy the defect of mind is always associated with a variety of defects of body which can be met by the ordinary resources of the physician and need not be further discussed here. Abundance of good food, warm clothing, healthy surroundings, useful employment, varied amusements, and the attention and supervision of kindly and skilled attendants, are here, as in all varieties of insanity, the main indications in treatment.

Idiots should be treated in separate wards in asylums, or in institutions devoted to their care, and should not, as is too often the case, be associated with adults, much to the detriment of both. Among the most useful means of treatment, may be mentioned classes for education in reading and arithmetic, sometimes drawing and music; for the patients of suitable physique, drilling, gymnastics, and out-door games, the teaching of trades, such as mat or brush-making, printing, or carpentry, at which occupations some idiots evince extraordinary mechanical skill. Dancing and theatricals will be appreciated by a large number of cases. But the physician must be contented with moderate improvement for he is dealing with an organism whose potentialities are limited. The most important question will often be whether the patient should be kept at home after the age of five. For the sake of the other children, removal to a suitable institution is to be advocated, and the case will benefit by the systematic training, and will not be discouraged by the constant comparison with normal childhood which is unavoidable in home treatment.

GEORGE REVINGTON.

ILLUSION.—Illusions are false perceptions of objects actually present to the senses, as distinguished from hallucinations where there is no external stimulation of the senses. The distinction is somewhat artificial, as no place is so still or so dark, but that some stimulation of the senses takes place, and so far as this is true, all hallucinations are illusions. Illusions become evidence of insanity when they cannot be corrected by the reason.

IMPETIGO (*I. contagiosa*; *Por-rigo*).—An acute, inflammatory, contagious, pustular disease most frequently met with in children.

The term is employed by many dermatologists to include two clinically separable pustular disorders, the one belonging to the eczema group (*E. impetiginosum*) and characterised by abundant pustulation without infective characters; the other a specific contagious disorder. It is more accurate to limit the term to the latter disease.

Impetigo is characterised typically by the rapid outbreak of vesicles which quickly become pustules. The pustules are large, flat, occasionally umbilicated, and are surrounded by a narrow, deep-red areola; they contain sero-purulent infective fluid which, on being conveyed, by the hands or otherwise, to other parts of the body or to other persons, reproduces the eruption. The pustules soon rupture, their fluid contents dry up to form dirty, thick, yellow scabs and crusts; by the coalescence and fusion of individual pustules extensive scabby areas are formed. The neighbouring lymphatic glands become enlarged and tender, but seldom suppurate. There is little or no pain, and no itching, unless the condition be secondary to other itching diseases (especially pediculosis and scabies), as is very frequently the case. In the course of two or three weeks the crusts fall off spontaneously, leaving a red, glazed base which rapidly heals without scarring, but considerable pigmentation may persist for some weeks.

The disease is very common on the scalp, face, hands, feet and genitalia of children, especially among the dirty and ill-fed children of the poor. It frequently affects several members of the same family, and becomes, in a certain sense, epidemic among school-children. The dermatitis provoked by pediculosis and scabies, by scratching in prurigo and urticaria, or even in simple eczematous eruptions, is liable to become impetiginous, the transition being marked clinically by the development of infective properties in the pus. Impetigo often follows vaccination, the pus which has developed infective properties being inoculated elsewhere by scratching.

Various observers are not agreed as to the exact specific element; some describe mycelial threads in the base of the pustules resembling those of trichophyton tonsurans, others describe cocci, whilst others, though they affirm the infectivity of the condition, have failed to discover any pathogenic organism.

Treatment is usually rapidly successful, but relapses are common unless the child be isolated, which is rarely possible.

Crusts and scabs ought to be removed by poultices, or rags soaked in olive oil, and ammoniated mercury ointment applied to the exposed surface, diluted if there be very extensive excoriation or active inflammation. Pediculi must be exterminated and scabies treated as elsewhere described. Cod-liver oil and iron are often beneficial.

J. J. PRINGLE.

INCUBATION is the development of a disease, and the period of incubation is the time which elapses between the exposure to the poison and the first symptoms of the disease. It is sometimes spoken of as the latent period. It varies greatly in the several infectious disorders, and its probable duration will be found under the different diseases. (See also Table, p. 187.)

INFANTILE PARALYSIS (*Acute Anterior Polio-myelitis; Acute Atrophic Paralysis; Essential Paralysis*).—Paralysis of one or more limbs or of groups of muscles coming on suddenly, and soon followed by rapid wasting of the paralysed muscles, with abolition of their reaction to the Faradaic current. The affection is almost peculiar to childhood.

Symptoms.—In some cases the disease begins with appalling suddenness; the child, if old enough to walk, falls down whilst crossing the room, and cannot get up. It is then found that one or both legs are paralysed. Sometimes the discovery is made in the early morning, nothing having occurred during the night to attract the attention of the nurse, or the child may have been restless and feverish. Sometimes it follows in the wake of one of the exanthemata, or appears to be the consequence of an accident. In some cases it is preceded by a definite illness of one or more days' duration, in which no symptoms calculated to raise alarm are observed; and just as the child seems to be getting well it is found that one leg or one arm is not being used. In very young children convulsions are often present in this premonitory illness; and in cases where all the limbs have been paralysed, the symptoms have sometimes resembled those of meningitis.

The paralysis is absolute and complete from the first; that is to say, it never spreads, though it is usual for it to become less marked in the course of a few days. The leg is more often affected than the arm, in the former the tibialis

anticus and extensor group of muscles being most commonly picked out; in the latter, the deltoid, the quadriceps adductors and glutei are less often attacked, the hamstrings not infrequently escaping. Both legs are more often attacked than an arm and a leg, whilst it is decidedly rare to see both arms alone affected, but not very uncommon to find the paralysis attacking both legs and one arm. Even when it seems quite general at first, it rarely remains so. It is believed that the muscles of the scalp, eyeballs, ears, pharynx, larynx, and the sphincters of the rectum and bladder always escape, and the cranial nerves are hardly ever the seat of the disease. Sensibility is never impaired, but the superficial and deep reflexes are at once lost. Some degree of pain and tenderness, especially in the neighbourhood of the joints of the paralysed limb, is common, and may persist, even for a month, in a gradually diminishing degree, but, as a rule, no pain is complained of whilst the child is undisturbed.

Usually in the course of a couple of weeks it is seen that the muscles are not only very flabby, but also that they are wasting, and that the limb is distinctly thinner than the other. This atrophy proceeds rapidly, and if the paralysed muscles be tested electrically, it will be found that they do not react to the induced current, but act normally, or even excessively, to the constant current (the reaction of degeneration). This change is usually present as early as the end of the first week. The blood-vessels of the affected part are contracted, and consequently the limb is always colder than its fellow, and has a somewhat livid colour, but no nutritive disturbances of the skin occur.

In long-standing cases the whole nutrition of the limb will be found to have suffered, and in consequence it is smaller in all its dimensions, the arrest of the growth of the bone being sometimes quite out of proportion to the extent of the muscular paralysis. After a time contractures are very apt to occur, not, as was formerly supposed, owing to the action of the unopposed healthy muscles, but from the influence of pressure or the weight of the body; of these, talipes equinus and equino-varus are the best examples.

There is a certain tendency to spontaneous recovery, but, unfortunately, it never proceeds very far. It is rare for a limb not to show some sign of improvement in the course of the first few weeks;

it is still more rare for anything approaching complete recovery to take place spontaneously. All the fibres are not paralysed in an affected muscle, and the chances of recovery depend on the possibility or otherwise of developing the healthy fibres. In too many instances for it to be a mere coincidence, it has happened that when the patient has reached adult life, he has become the subject of progressive muscular atrophy, but the cause of this sequence is quite unknown.

Diagnosis.—Until the paralysis is declared it may be impossible even to surmise the nature of the affection. In the early stages, hip disease, the so-called congenital dislocation of the hip, and syphilitic epiphysitis of the head of the humerus or femur, are the affections which might give rise to a similar set of symptoms. The obvious pain, heat, and swelling in the neighbourhood of the joint would show the true nature of the malady, whilst in regard to congenital dislocation the amount of wasting would have to be taken into consideration; if this were inconsiderable the probabilities would be in favour of the congenital affection. When rickets especially affects the muscular system, the condition of the legs may present some resemblance to infantile paralysis, but a very slight amount of care will suffice for the recognition of points of difference. If the paralysis be of hemiplegic form, it is probably of cerebral origin, and this will be confirmed if it be found that the reflexes are present, that the wasting is only slight, and that there is a tendency to rigidity of the muscles. In all cases the reaction of the paralysed muscles to the induced current should be ascertained, and it may be necessary to resort to the use of chloroform for this purpose.

Pathology.—Changes in the anterior cornua of the grey matter of the spinal cord, the exact nature of which in their earliest stages is unknown, are the cause of the paralysis and muscular wasting. The ultimate result is shrinking and degeneration of the multipolar cells, with gradual disappearance of their processes, and often of the remains of the cell. The neuroglia also, especially in the immediate neighbourhood, shows an increase of fibrous tissue; wasting, and sometimes fatty degeneration of the nerve tubes, is found in the anterior roots. To the naked eye the only change will be a slight paleness, or a dull pink colour, of the grey matter, and in long-

standing cases the entire cornu, or possibly the half of the cord, will be wasted. These changes are found in the lumbar or cervical enlargement according as the legs or arms were affected. In some cases, fatal at an early period, the damaged area of the cord has been found soft and vascular, pointing to the presence of inflammatory action, but whether the inflammation begins in the motor cells or in the neuroglia has not yet been determined. In others, the appearances have suggested that a small hæmorrhage has occurred, a mode of onset that would fit in well with the symptoms sometimes observed. The muscles at first appear simply wasted, they then lose their striation, and finally undergo degeneration. In long-standing cases, atrophy of the paracentral lobule in the opposite cerebral hemisphere has been found.

Ætiology.—The disease may occur at almost any age, but is most common between the sixth and eighteenth month. Boys and girls seem equally liable to it. It occurs much more frequently during the summer months, perhaps because at this time less care is taken to protect children from the effects of a chill, but little is definitely known about the exciting causes. The disease has sometimes followed an injury, and occasionally it has come on during convalescence from one of the exanthemata. Robust children, equally with the weakly, are liable to be attacked, nor does inherited neurotic tendency seem to predispose especially to the affection. It has been suggested that the careless way in which children are lifted by the arm may be a cause, but the obvious reply is that the leg is much more often affected than the arm. The disease is not more common amongst the children of the poor than those of the wealthy.

Treatment.—During the acute stage—*i.e.*, for the first week or so after the paralysis is discovered—the child should be kept quiet; and some recommend that it should not be allowed to lie on its back, with a view to diminish any tendency to congestion of the cord. A succession of blisters applied to the spine near the seat of the disease is a form of treatment which experience has proved to be more efficient than any other. If there be no fever, ordinary diet may be allowed, and internally the liquid extract of ergot in 3-minim doses, tincture of belladonna or liquor strychninæ in 1 or 2 minim doses, or 1-grain doses of iodide of potassium, may be given to an infant twelve months old. At the end

of a month no further improvement can be looked for on these lines, and cod-liver oil and iron should be used instead. After the first week the child should be taken out every day, if the weather permit, and as soon as the limb can be freely handled without pain, which will often not be until after the lapse of three or four weeks, systematic massage and the use of electricity should be commenced (see the articles under these headings). By these means we may hope to develop the muscular fibres of which the nervous centres are not destroyed, but are merely inactive from disuse, and to maintain the circulation in the paralysed muscles. From the first the greatest care must be taken to keep the limb warm. It is never too late to commence this treatment, though of course the earlier it is begun the better the prospect, but even when two or more years have been allowed to elapse, persistent treatment has been very successful. A case should not be given up as hopeless until after at least a year of systematic treatment. Every effort should be made to overcome deformities by manipulation, and by the use of instruments; if these measures fail, the aid of the surgeon should be sought.

JOHN ABERCROMBIE.

INFLAMMATION.—Inflammation is a process which is very difficult to define in the present state of our knowledge. Dr. Burdon Sanderson has given the following definition: "The succession of changes which occurs in a living tissue when it is injured; provided that the injury is not of such degree as at once to destroy its structure and vitality." Lately, owing to the observations of Mentschikoff, some authorities consider the succession of changes as "the method by which an organism attempts to render inert noxious elements introduced from without or arising within" (Bland Sutton).

From time immemorial inflammation has been considered the most important phenomenon in disease. Medical terminology indicates how closely inflammation is associated with nearly all morbid processes, and it is not too much to say, that a correct understanding of the pathology of inflammation, is the foundation of all medical and surgical knowledge and the key to the scientific treatment of disease.

The four cardinal symptoms of inflammation—*calor, dolor, tumor, rubor*—were enunciated by Celsus; to these may be added *functio laesa*. Galen explained

the redness by an increased flow of blood to the part, and the swelling he attributed to exudation.

Little was added to our knowledge until the time of John Hunter: many of the principles of the pathology of inflammation held by him are now proved to be true. The cellular theory of pathology of Virchow, led to the adoption of erroneous views as to the origin of pus corpuscles, the most important being a belief that they arose by multiplication of the fixed connective-tissue corpuscles. Serious objection was raised to this theory by Addison and Waller, both of whom observed and recorded the fact, that the white corpuscles migrated from the blood-vessels in large numbers in an inflamed tissue, and moreover, they expressed the belief that the migrated leucocytes became pus corpuscles.

The honour of establishing the modern theory of inflammation is entirely due to Cohnheim, who by a careful series of microscopical observations, elucidated the succession of changes which occur in an inflamed tissue. He used the mesentery, the web of the foot and the tongue of the frog. The inferences he drew from his observations have been proved to hold good when applied to warm-blooded animals, for similar changes have been described in the bat's wing, in the mesentery of dogs and rabbits, and even in the human lip, when these structures are injured.

With this brief introduction we shall now consider the microscopical changes which occur in an inflamed tissue; for convenience sake they may be considered separately under three main headings, but it must be clearly understood that they occur conjointly, even from the very onset of inflammation.

I. Vascular Changes.—All tissues are extra-vascular, the abundance of the blood supply depending upon their functional activity, consequently tissues having a purely mechanical function, are supplied with few vessels or derive their nutriment from vessels which are not situated in the tissue itself, but in the immediate neighbourhood. These so-called non-vascular structures are the cornea, cartilage, and elastic tissue; they are, however, capable of undergoing inflammation, and the vascular changes can be observed in the circumjacent vessels.

If the mesentery of a brainless, curarized frog, be examined under the microscope, the process of inflammation can be readily studied. After 15 to 20 minutes

simple exposure to the air induces inflammation, manifested first by *dilatation of the arteries*, then of the veins, and lastly and to a much less degree, of the capillaries. With the general vascular dilatation occurs also an acceleration of the blood stream, the so-called afflux or determination of blood to an injured part. The acceleration does not last long, and is followed by a very marked slowing or *retardation* of the circulation. The vessels remain dilated, and numbers of capillaries which previously were not seen, now become visible, the small arterioles exhibit *pulsation* and each individual corpuscle in the smaller vessels can be distinctly recognized.

At the commencement of the observation, it is noticed that the blood in the vessels exhibits a central axial stream containing the corpuscles and a periaxial stream of plasma. It has been proved experimentally, that when fluids containing particles of different specific weights be forced through tubes, if the rate of flow on the one hand be sufficiently rapid, the solid particles will form an axial stream, and the fluid, the periaxial stream; if the rapidity of flow on the other hand be diminished, the lighter particles will be thrown out into the periaxial stream. This seems to explain the change which occurs in the periaxial stream of the vessels, for as the circulation gets slower in the inflamed mesentery, so the white corpuscles, which are specifically lighter than the red, are seen collecting in increasing numbers in the periaxial stream of the smaller veins, forming a continuous layer one or two rows deep, like an epithelial lining.

After a time the flow has become so slow in the capillaries that only an occasional *oscillation* is seen synchronous with the pulse, eventually culminating in *capillary stasis*; finally, coagulation of the blood in the vessels leads to thrombosis, although it seems that after stasis has occurred the blood may remain fluid for several days.

II. Exudation of Fluid and Escape of Blood-corpuscles.—The leucocytes, which in proportion to the slowing of the circulation have been accumulating in the periaxial stream of the veins, commence to *migrate*. The process is termed *diapedesis*.

A white corpuscle, if watched, will be noticed to bulge out the vessel wall laterally; after a short time it will have made its way through the wall, and it will now hang like a little pear-shaped mass with its stalk attached to the vessel

wall: eventually this is sundered and the corpuscle is free to wander in the tissues. Great numbers of white corpuscles escape in this way, usually many more than the red, but the latter escape in great abundance if the injury be severe. Leucocytes migrate from the capillaries as well as the veins.

An escape of fluid from the vessels is always taking place, even in health, but in inflammation not merely is the transudation increased in quantity, but it is changed in quality, it is richer in albumin and capable of coagulation. In fact after a short time a *false membrane* can be removed from the surface of the mesentery.

III. Tissue Changes.—These are not so readily observed in an inflamed area as the vascular changes. They depend upon several conditions—firstly, upon the direct effects of injury; secondly, upon the pressure exerted upon the tissue elements by the exudation products; and thirdly, upon disturbance of the circulation and nutrition.

The tissues of an inflamed part are softer, owing to the structural element being separated by the fluid exudation, and the lymph spaces are crowded with leucocytes, and perhaps red corpuscles. The ultimate degree of destruction of tissue elements mostly depends upon the degree of re-establishment of the circulation in an inflamed area.

Regenerative processes may occur in the neighbouring cells of an inflamed area, by which the tissue may be repaired. This is a process of cell multiplication, but Sinfleben has shown that it occurs independently of inflammation. Moreover, tissue repair by cell multiplication on the one hand, and intensity of inflammation on the other, proceed in an inverse ratio.

The Cardinal Signs of Inflammation are—

(1) *Rubor (Redness)*.—This depends upon the increased afflux or determination of blood to the injured part. Frequently, owing to dilatation, numbers of vessels hitherto unseen become visible; this is termed *injection*. If the vessels are not recognizable, as in inflammation of the skin, the redness is *diffuse*. The redness is usually of a dark tint, tending even to purple; this is owing to the blood being contained more in the veins, and also to the slowing of the blood stream by which the corpuscles contain less oxyhæmoglobin.

The redness depends also upon two other conditions viz., capillary stasis

and the escape of red corpuscles. Either of these conditions produces redness, which will not disappear on pressure. Hæmorrhages frequently give it a *punctiform* appearance. Much transudation will diminish the degree of redness, therefore the sign "rubor" is often most marked in the earlier stages of inflammation.

(2) *Tumor (Swelling)*.—This is caused by two factors, *vascular turgescence* and *exudation*, the latter being much the more important.

There is a great increase of exudation from the vessels in inflammation, and this leads to an increase of the lymph stream. Swelling of the part occurs if the ratio of absorption by the lymph channels be not proportional to the increased exudation, and the degree of swelling depends upon the relation of these two factors. This exudation is not due to resistance to the flow of blood through the vessels as in venous obstruction, because we know that actually a larger flow of blood through the veins occurs in an inflamed part. Neither is it due to increased pressure in the vessels, but it is owing to *damage of the vessel wall*, which is the essential lesion of inflammation. In proportion to the injury the vessel wall loses its power of resistance to the passage of fluid and corpuscles. As Cohnheim puts it, alteration of the filter not only allows of quantitative changes in the filtrate, but also a very important qualitative change.

Inflammatory lymph has a higher sp. gr., contains more albumin, and more white corpuscles; it has, consequently, a greater tendency to coagulation than the exudation from venous obstruction. This proves that the vessel leaks in a different manner in the two cases. In severe forms of inflammation, especially when occurring in very vascular structures—*e.g.*, the lungs, the kidneys, and the heart—there may be an extensive escape of red corpuscles, giving rise to *hæmorrhagic exudation*.

The extent and form of swelling which may occur in an inflamed part greatly depend upon the anatomical structure. The exudation occurs primarily into the connective tissues surrounding the vessels, and if absorption does not take place, it will accumulate in the inflamed area, and will naturally travel along the lines of least resistance. In pneumonia it accumulates in the air-sacs. Inflammation of serous membranes and joints is attended with exudation into the serous cavities. Inflammation of the

vagina, nose, respiratory tract, alimentary canal, bladder, and kidneys, may be attended by little or no swelling, owing to the free exit which the inflammatory exudation products find from the body. We therefore see that although swelling has for its origin but one cause, yet in the mode of its appearance it is one of the most variable of signs.

(3) *Dolor (Pain)*.—The degree and intensity of the pain depends upon the *abundance of the sensory nerves* in the affected part, the *capability of distension* of the organ or tissue, by the exudation, and, lastly, upon the *amount of exudation*.

In organs which contain but few sensory nerves, *e.g.*, the kidneys, severe inflammation may occur without much pain. In periostitis, owing to the difficulty the exudation has in accommodating itself, the pressure upon the sensory nerves is great and the pain intense. The character of the pain varies considerably; often it is throbbing. This depends upon the increased pressure on the sensory nerves produced by the pulse wave in the affected part. When the part is dependent, an increase of the affluent blood is favoured by gravity, and the effluent stream is retarded, conditions which favour exudation and thus account for the increased pain. Pain must, however, be considered conservative, for it tends to curative measures, such as rest, &c. Inflammation of structures in which the sensory nerves have lost their function, or have been destroyed, are usually attended with disastrous results.

There is a general belief in the existence of trophic nerves, and physiologists teach that there are two sets of nerves presiding over the nutrition of tissues, viz., katabolic and anabolic, the former controlling destructive metabolism, the latter constructive. Whether we explain the following pathological facts by the theory that trophic fibres exist in nerves, or rather believe that they only show the truth of the statement that structures deprived of their sensory nerves are more prone to inflammation, it matters not. Injury to the fifth nerve leads to sloughing of the cornea; herpes zoster follows neuritis, and bed-sores occur after injury of the brain or spinal cord; rarefying osteitis may follow injury of nerve roots.

(4) *Calor (Heat)*.—An inflamed part feels hot to the patient, but as John Hunter pointed out, the temperature is never really above that of the rectum, or of the blood generally. If there were actually more heat produced in an in-

flamed part, its temperature would not be raised on this account, because the heat would be distributed over the whole mass of blood in the body.

If inflammation be produced experimentally in the foot of an animal, the temperature of the inflamed part will be a little higher than the corresponding member of the other side, but this may be explained by the increased afflux of blood. In unilateral pleurisy in rabbits, the temperature of the inflamed cavity is never above and is usually below the healthy one. Consequently, the slight increase of temperature in the former case is due to the increased flow of blood to the part. The burning feeling may be explained by the fine degree of appreciation for slight variations of temperature in the blood circulating in the skin of the inflamed part possessed by the sensory nerves, when contrasted with the sensations from the surrounding healthy structures.

Punctio Læsa.—Impairment or loss of function of an inflamed part may be added to the four cardinal symptoms.

Glands may be unable to secrete, muscles to contract, nerves to conduct, and other structures to perform their functions, or, at any rate, to perform them in a normal manner. This may be temporary or permanent according to the severity of the inflammation and the nature of the tissue. The highly differentiated tissues of the central nervous system are incapable of regeneration.

Varieties of Inflammation.—The essential lesion of inflammation is damage to the vessel walls. The extent of injury will determine both the amount and characters of the exudation and the number of corpuscles, both red and white, which will escape.

The varieties of inflammation may be said to depend upon three factors. (1) *The nature and intensity of action of the noxious agent.* (2) *The duration of its action.* (3) *The anatomical structure of the inflamed tissue.*

The following varieties depend upon the nature of the exudation products:—

(1) *Serous Inflammation.*—The injury is slight; as a result, the exudation, although it contains more albumin than a passive transudation, nevertheless, owing to its not containing many leucocytes, does not coagulate, or, at any rate, only flakes of fibrin are formed. The best examples are afforded by chronic effusions into serous cavities—*e.g.*, the pleura and joints. When it infiltrates the substance of a solid organ or struc-

ture, it gives rise to *inflammatory edema*. In impoverished conditions of the blood, even if the inflammation be comparatively severe, the exudation may be serous in character.

When a *mucous membrane* is mildly inflamed, the exudation escapes from the surface, and such a condition is termed *serous catarrh*.

(2) *Sero-Fibrinous.*—This condition arises when the injury, although more severe than the above, is less so than the following form. The exudation is fluid, but contains a very considerable quantity of fibrinous flakes.

(3) *Fibrinous or Croupous.*—Typical examples are afforded by the serous membranes—pleura, peritoneum, pericardium—and mucous membranes. The exudation contains large numbers of white corpuscles, and the fluid is rich in fibrinogen, consequently it tends to form fibrinous layers on the surface of the inflamed membranes. The meshwork of fibrin encloses numbers of leucocytes, and this constitutes “lymph.” An adjacent serous surface may get coated with similar lymph, and the two uniting form an *adhesion*. This, by organization, may become transformed into connective tissue, which, later on, will contract.

The red corpuscles are usually few in number, because they remain around the vessels from which they have escaped; but in croupous pneumonia, owing to the proximity of the alveoli to the inflamed vessels, the exudation contains large numbers of red corpuscles. Croupous membranes may be formed upon inflamed mucous surfaces. They consist of an interlacing meshwork of fibrin enclosing leucocytes, or pus corpuscles, *e.g.*, plastic bronchitis and laryngitis.

(4) *Purulent or Fibrino-Purulent.*—In nearly all cases the inflammation is infective, micro-organisms being present. The exudation consists of a liquid plasma containing *pus corpuscles*. When a cavity is formed by the destruction and dissolution of the inflamed tissues, the cavity being occupied by pus, an *abscess* results. If the tissue destruction be superficial, and the part in which there is a solution of continuity of tissues secrete pus, we have an *ulcer*. A fibrino-purulent exudation is a condition in which the pus contains flakes of fibrin.

Pus is a thick creamy opaque yellow, or whitish-yellow fluid, of sp. gr. 1030–1033, and alkaline reaction; it is slightly viscid and possesses a faint odour. It does not coagulate spontaneously, although containing a very considerable

quantity of albumin. That pus, which is a derivative of the blood, should remain fluid, can be best explained by assuming that the micrococci and staphylococci found in pus have a peptonizing action upon the plasma.

Pus contains 10-15 per cent. of solid matter, of which two-thirds are albumin and the remainder salts and fatty matters. If pus be allowed to stand it separates into a yellow layer of pus corpuscles and a supernatant liquid, *liquor puris*.

Pus-corpuscles are leucocytes which have undergone a process of degeneration. As a rule they have no power of amoeboid movement, but are spherical masses of granular protoplasm, containing a nucleus, often showing indications of division into two or three nuclei. By the addition of acetic acid the nucleus is rendered more evident, the surrounding cell substance clearing up.

(5) *Hemorrhagic Exudation*.—When the exudation contains a sufficient number of red blood corpuscles to be apparent to the naked eye, the indication is either that there is a loss of vital resistance in the vessels, due to some constitutional disease or defect, *e.g.*, diabetes, hydræmia, &c., or a very intense action of the noxious agent which has led to the inflammatory process and the consequent damage to the vessel walls.

(6) *Putrid or Gangrenous*.—When the exudation undergoes putrefaction from the action of bacteria, the inflammation is very severe and the tissue destruction great. The colour of the diseased part may be grey, greenish or purplish-black, due to chemical changes. Gases may collect in the tissues, or escape, giving rise to foul odours.

(7) *For Diphtheritic Exudation, see DIPHTHERIA*.

Any tissue in the body, with the exception of a few epidermoid structures, may be the seat of an inflammation.

Varieties of Inflammation according to Anatomical Structure of the Tissues.—*Superficial*.—An inflammation of a free surface such as the mucous membranes, serous membranes, or the skin, is termed superficial. In this form the exudation either escapes from the body, collects in a space or cavity, or undergoes deposition on the inflamed surface.

Parenchymatous.—This term is applied to an inflammation of solid organs, such as the lung, kidney, or liver. The exuded liquid collects in the lymph spaces of the tissues and gives rise to an *infiltration*.

The process may be acute or chronic; as a rule the inflammation is intense and the essential elements of the organ exhibit morbid changes from the onset of the process, thus differing from the next variety.

Interstitial.—This form of inflammation is much more frequently a chronic process, although it may occasionally be acute. The changes are limited to the fibrous tissue framework of the organ, and the essential elements do not suffer until later on in the disease.

It is usually a question of degree rather than of difference in the process, and the distinction applies especially to certain organs, where the fibrous framework is well differentiated from the essential cell elements, *e.g.*, the liver, lungs, and kidneys.

The results of inflammation are:—(1) Resolution, (2) Suppuration with discharge or caseation, (3) Regeneration, (4) Formation of granulation tissue, (5) Cicatrization.

(1) *Resolution*.—If the inflammation be not severe, and the injurious agent does not continue in operation, the damaged vessel wall recovers, the circulation is renewed, and the exudation products are absorbed by the lymphatics.

(2) *Suppuration*.—If on the other hand the injury to the vessel be severe, and pus have formed, giving rise either to an abscess or a purulent exudation, one of two events may happen: the pus may be discharged, leaving the abscess cavity to be filled up by tissue regeneration, or the pus may undergo changes which eventually lead to the formation of a cheesy mass (*caseation*), and later this may become *cretaceous*. Generally speaking, such a substance acts as a foreign body and gives rise to productive inflammation in the adjacent tissues by which means it becomes encapsuled.

(3) *Regeneration*.—Repair is effected by the multiplication of the surrounding healthy tissue elements. Epithelium produces new cells by division, muscle forms fresh fibres and periosteum new bone. The ganglia of the central nervous system cannot however undergo regeneration after destruction, probably on account of differentiation of function of these master tissue elements.

Ætiology.—The causes of inflammation may be considered under two main headings; (1) *Intrinsic* or *predisposing* and (2) *extrinsic* or *exciting*. The former is a variable factor in every tissue or organ and in every individual. It is an unknown factor in every human being,

depending upon the family antecedents and the past life of the individual, and is perhaps more important to the physician than the extrinsic or exciting cause.

The causes with which the physician has to deal are often insidious and obscure. As a rule the exciting agent is only a part of the cause, *e.g.*, the morbid inflammatory conditions which arise in gout. The cause has been in operation for years, and it is generally only when it is far advanced and gives rise to pain that the physician is consulted.

Idiopathic inflammations are more and more regarded with suspicion as to their existence, pericarditis and pleurisy are often said to be idiopathic in origin. Cold and exposure to wet, such as by immersion, undoubtedly do produce inflammation of serous membranes; more frequently, however, it is the individual whose tissues have a predisposition to inflammatory affections of these structures, owing to a rheumatic or some other taint.

Peritonitis again is often said to arise idiopathically, most of these cases, however, are secondary to inflammation elsewhere. Females infected with gonorrhœa may die of peritonitis by extension of the infective inflammation along the Fallopian tubes: such cases may be misunderstood and termed idiopathic.

We shall only here briefly attempt to indicate the more important *exciting causes* of inflammation. They may be classified as follows:

(1) *Physical*.—Heat, burns, scalds, exposure to the sun, cold, exposure to damp, immersion. The latter are among the most common exciting causes of inflammation of the viscera and serous membranes.

(2) *Mechanical*.—Direct injury, wounds, contusions, fractures. The following are, however, some of the more important causes with which the physician has to deal:—Improperly masticated food and indigestible food may set up gastritis; the inhalation of irritant particles into the lungs will produce pulmonary fibrosis, a disease common amongst miners, millers, and knife-grinders.

Inflammation may be due to parasites affecting the skin (*acarus*), the muscles (*trichina*) and the viscera (*hydatids*). Frequently in such cases the inflammation may be sanative, the parasite becoming encapsuled by the inflammatory product. Again, strain combined with defective nutrition plays a most important part in cardio-muscular inflammation and subsequent degeneration.

(3) *Chemical*.—We may divide these causes into two classes: local, as in the bite of an insect, owing to the irritation produced by formic acid; or, again, the application of irritating or corrosive fluids to delicate structures. The most important chemical excitants of inflammation are those which, owing either to defective elimination of waste products from the system, or to the circulation in the blood of poisons such as alcohol and lead, give rise to chronic inflammatory changes around the small vessels, and subsequently to the production of fibrous tissue and atrophy of the essential elements of the organ. The effect produced by the poison is particularly marked in those organs where the irritant is most concentrated—*e.g.*, cirrhosis of the liver in chronic alcoholism, and cirrhosis of the kidney in retention of imperfectly oxidized nitrogenous waste matters.

Many poisons when taken into the system tend to produce local inflammation—mercury causes stomatitis; cantharides, nephritis; potassium iodide affects the mucous membranes. These effects may be explained by the elimination of considerable quantities of the drug by these structures.

The above causes all tend to produce simple inflammation, that is to say, if the cause be removed, the inflammation will subside, or at least it will not progressively increase.

(4) *Infective Causes which depend upon the Action of Living Organisms*.—Prof. Hüter, asserted that inflammation could not occur without micro-organisms. Most authorities believe that true creamy pus can only be formed when micro-organisms are present, and no one doubts that in most cases suppurative inflammation is the direct result of the action of micro-organisms, particularly micrococci, which by their peptonizing action prevent the formation of fibrin. A simple inflammation may become suppurative owing to infection—*e.g.*, simple endocarditis becomes ulcerative and may give rise to a condition like pyæmia; this has been proved to be due to the presence of micrococci in the vegetations.

There are two main groups of factors in the production of an infective inflammation; they are, the *nature and the number of germs introduced, and the soil*.

The mode of production of inflammation by germs varies considerably. They may produce a local inflammation, which may or may not become general, or they may from the outset produce a general

inflammatory process, but usually they then attack some particular structures more especially.

The micro-organisms may be specific or non-specific, the former are especially prone to attack certain tissues in preference to others—*e.g.*, the bacilli of anthrax attack the spleen; those of lepra, the skin; and the bacillus of tubercle affects particularly the lymphatics of internal organs.

The inflammation which is excited by micro-organisms is probably due to the fact that they multiply wherever they find a suitable nidus, and act as foreign bodies, setting up local inflammatory processes. These foci, owing to the dissemination of the germs by the blood and lymph streams, may be innumerable, as in general tuberculosis. During their growth and multiplication various chemical products originate, and these play a very important part, as we have already seen in the formation of pus.

The soil is of almost as much importance as the number and nature of the germs.

In general non-specific inflammations we know that they are much more likely to be suppurative if the vital resistance of the tissues of the body has been lowered, as, for example, by alcoholism, chronic Bright's disease, diabetes, and malnutrition. Moreover, it has been shown that animals suffering from inflammation artificially produced, when fed upon putrid meat, become affected with an infective suppurative inflammation.

Again, the influence of soil is strikingly shown in the hereditary tendency of certain races and individuals to particular specific inflammations. Among animals also we have a remarkable instance of hereditary immunity in the Algerian sheep, which cannot be inoculated with anthrax.

Latterly, Mentschikoff and others have shown that the white corpuscles of the blood are the essential agents in the destruction of micro-organisms. Direct observations prove this; moreover, we know that in suppurative inflammation and in tuberculosis the white corpuscles are greatly increased in number.

It is concluded that the white corpuscles migrate from the vessels in inflammation, for the purpose of removing the living or dead matter which is either the cause or the result of the inflammatory process. Mentschikoff has also demonstrated that the leucocytes may be observed in the tadpole's tail devouring

the useless tissues, and their protoplasm may be seen to be loaded with the debris. Moreover, he has observed the process of ingestion of bacilli and other micro-organisms by the white corpuscles. These observations tend to show that an essential part of the process of inflammation is a struggle between the leucocytes and foreign matter, whether it be dead or living.

In the case of simple inflammation the white corpuscles have merely to remove the products of tissue-death and disintegration. In the case of a local infective inflammation they have to engage in a death-struggle with the micro-organisms. If the leucocytes be victorious, the local suppurative inflammation terminates in an abscess, which may discharge its contents or dry up and become encapsuled. On the other hand, should the leucocytes be unequal to cope with the micro-organisms, on account of their own inherent low vitality, or on account of the number and virulent potentiality of the germs, then the infective process will become general.

F. W. MOTT.

INFLUENZA.—A specific epidemic disease, sometimes marked by catarrh of the naso-pharyngeal and pulmonary mucous membrane.

Symptoms.—The onset of illness is always sudden, and is marked by chilliness or actual shivering. From an early period there is marked prostration, the patient feels faint and giddy, he is sometimes drowsy, and may fall suddenly down. Sneezing, followed by a watery discharge from the nostrils, may be an early symptom; the eyes are red and watery; the fauces are also red. The fever is high at first, and the skin dry, but, in a mild case, it soon becomes moist; the pulse is rapid and small. Cough, either hard and dry or with a little secretion, is usually present; with this there may be some rhonchus and sibilus. There is complete anorexia and nausea, and loss of taste. Severe headache and a pain in the eyes are almost always present. Severe pains, especially in the back, chest and limbs, may constitute the most prominent features, all catarrhal symptoms being absent. The urine is scanty and high-coloured. The above is a description of a mild attack, such as usually lasts from three to five days.

The case may be more severe owing to an exaggeration of any of the symptoms, and any imprudence during convalescence may be followed by a relapse in

which, instead of simple bronchial catarrh, there may be capillary bronchitis or broncho-pneumonia. Gastric symptoms may predominate, and there may be constant sickness, and perhaps jaundice, with diarrhoea and blood-stained motions.

As a rule, recovery is complete; but in those who are predisposed to that affection an attack may be the starting-point of pulmonary tuberculosis. The aged and the very young often succumb to the lung complications, but in the case of an adult in good health an attack rarely gives any occasion for alarm. One attack affords no protection against subsequent infection.

There are no characteristic post-mortem appearances.

Etiology.—Influenza presents one of the most typical examples of an epidemic disease, and its spread is at times so rapid that in a very short period a large proportion of the inhabitants of a town or district may become affected. According to Hersch, in the great pandemics of 1833 and 1837, "many countries were smitten by the disease as if at one blow." In the first two months of the year 1833 the disease is said to have spread all over Russia; "in March it appeared in Poland, Bohemia, Northern Germany, Egypt, and Syria; in April it began to prevail in Austria; Hungary, France, Great Britain and Ireland; Tyrol, Dalmatia and Italy suffered in May, the Netherlands in June." Dr. Peacock states that more than one quarter of the whole population of London suffered during the epidemic of 1847-48. In Paris at that period the proportion is said to have been nearly one-half. Russia has been the starting-point of the disease in all the great pandemics, and in 1889 an epidemic, originating in St. Petersburg, spread to nearly all parts of Europe, and to America and elsewhere.

During the epidemic prevalence of the disease in any country, a similar affection has been observed among animals, cats, dogs, cows, and especially horses, having been its chief victims.

There is no periodicity about the epidemics, and they occur quite independently of season, climate or soil. A thick black fog has occasionally been observed to precede an outbreak of the disease. An epidemic may travel with the wind or against it; at times the rate of spread of the disease is very rapid, at others very slow. Epidemics rapidly attain their height and quickly

subside. Insanitary surroundings probably favour an outbreak of the disease. Although direct contact is not essential, the disease is, to a certain extent, contagious. It does not appear sporadically. It is presumably due to some living organism transmitted by the air and capable of reproducing itself very rapidly in the air. This has lately been identified by Dr. Siefert, of Würzburg, and named the "influenza-coccus." The organism is stated by this observer to be present in the expectoration from all the cases of the disease. The incubation period may be exceedingly short or may last two or three weeks.

The disease is said to occur more readily in women than in men, and in men than in children.

Treatment.—The patient should be kept in bed or in a warm room until convalescence is complete. Lowering treatment is not well borne; antipyrin, quinine or salicin may be given in the febrile stage, with an occasional saline purge. Lung complications should be treated upon general principles. Great care in avoiding exposure to cold is essential at all stages of the disease.

JOHN ABERCROMBIE.

INHALATION.—It has been definitely proved that not only gases, but also liquids and even solids, can be made to enter the lungs by the process of inhalation, provided that none of these be of an irritant nature. In the case of solids and fluids it is likewise essential that they should be in a state of extremely fine division. Various remedial agents can thus be brought directly into contact with the mucous surfaces of the upper and lower air passages, and are capable of absorption into the general circulation, through the blood-vessels of the lungs. They may, therefore, have a local action upon the respiratory tract and a general action upon other organs. The influence of heat and cold may also be brought to bear directly upon the lungs by similar means.

Solids are rarely, if ever, employed by inhalation in lung affections, but are frequently used in the treatment of pharyngeal and laryngeal diseases. They are, however, much more effectively applied by insufflation through a straight or curved tube of glass or vulcanite, by which means they can be directed with accuracy upon the exact spot where they are required, without being distributed indiscriminately to all surrounding parts.

Liquids can only be inhaled when they are broken up into very fine spray. They can be employed at any temperature and may be found useful as a means of applying the influence of cold. Spray producers are in universal use and do not require special description. Two forms may be used for inhalation, the simple hand-ball spray producer and the steam apparatus on the principle of "Ziegler's spray."

The steam spray is best adapted for inhalation when it is desired to affect the larynx and bronchi, and to diffuse the medicament evenly over the mucous membrane.

The hand-ball spray producers are most useful in affections of the mouth, fauces, posterior nares or nostrils, where a local more than a general effect is desired. The spray may be directed through suitably curved tubes, of which Troeltsch's is at present one of the most practical forms. The liquids to be atomized by the hand sprays should be kept at a temperature of about 160°, as much heat is lost in the process of spraying.

In inhaling spray the lips must be widely separated, the tongue depressed and deep inspirations taken. The patient should be able to obtain a view of the whole of his pharynx before a mirror, and, until he can do this, inhalation of spray should not be attempted.

In using the steam spray inhalers it is advisable to collect the spray in a glass tube of about 1 inch in diameter and 4 inches in length. The end of this tube should be taken between the teeth, and the lips closed over it. The steam may then be freely inhaled without the annoyance of its diffusion over the rest of the face. Unless deep inspirations be taken, there is but little chance of the inhaled medicaments reaching the lower air-passages.

The position in which the patient sits is also of importance. The body should be fairly upright and the head slightly raised so as to render the angle formed by the mouth and the trachea as obtuse as possible.

Inhalation should always be practised in a room of equable temperature, and the patient should not leave the room for at least a quarter of an hour after the inhalation is concluded.

It is important that inhalation of medicated spray should not be practised for a long time without pauses for the respiration of fresh air. Four or five respirations in succession are quite

enough, and a pause should then follow of equal length.

Inclusive of these pauses, each sitting should not be prolonged for more than a quarter of an hour.

These observations may be taken to apply with equal force to the inhalation of medicated steam.

Gases and Vapours may be employed for inhalation either at the normal atmospheric pressure, or under increased or diminished pressure, and at any desired temperature. The simplest forms of inhaler for vapours at the ordinary atmospheric temperature are respirators, fitted with a small space in front capable of holding a piece of lint or of sponge on which the required drug can be poured. Volatile oils, ethers and spirits can best be inhaled in this way, but the inhalation must be long-continued and the apparatus so contrived as to cover both the mouth and the nostrils, and fitted with valves permitting the expired air to pass out of the inhaler without again coming into contact with the sponge.

The best form of inhaler for moist medicated vapour at a high temperature is that known as Mackenzie's "eclectic inhaler," by means of which a stream of air is drawn through medicated water of a fixed temperature, generally about 140° F., the mouthpiece being guarded by valves so that the same air cannot re-enter the inhaler after it has once passed out.

Steam, either medicated or plain, may be inhaled by means of Dr. Robert Lee's inhaler, in which the water is heated in a small spherical boiler, the steam escaping through a tiny pin-hole in the upper side. Two ounces of water are placed in the boiler, a few drops of the medicament to be inhaled are then added the top screwed firmly down, and the spirit-lamp placed underneath; steam will soon issue from the pin-hole with considerable force, and may be inhaled, with the precautions already indicated, through a glass tube of one-inch calibre. The metal tube generally supplied with this inhaler is apt to become too hot to be used with comfort.

A very simple inhaler for medicated steam can be constructed by placing the medicament in a medium-sized jug and pouring over it about half a pint of water at a temperature of 180° Fahr. The medicated steam arising out of the jug can be drawn into the mouth and nostrils very effectively by simply preventing its escape at the sides of the jug with the hands or by a folded towel.

Care must be taken, however, that not more than three inhalations are made in succession without a pause for the inhalation of fresh air.

These methods of inhalation are especially adapted where volatile oils have to be employed, a definite quantity of the oil being previously shaken up in a drachm of water containing $2\frac{1}{2}$ grains of light carbonate of magnesium.

In all forms of vapour inhalers where tubes are used it is important that they should be of wide calibre and that the nose should be closed, otherwise the inhalation may be reduced to a mere sucking process which will not carry the vapour beyond the mouth. Medicated cigars or cigarettes are sometimes used, and are undoubtedly of good effect in certain forms of spasmodic dyspnoea, but it is probable that their effect is due to direct absorption by the mucous membrane and not to any local action. In many instances the same drug given by the mouth has been shown to have an equally powerful effect.

Chambers have been devised to ensure the complete inhalation of medicated air, and consist essentially of small rooms or cabinets into which medicated vapour can be introduced, either as a spray or by suspension of cloths kept wet with the required solution, which is allowed to evaporate freely and is constantly renewed, or by an arrangement of fans blowing air through the medicated fluid directly into the chamber. By all these methods the air is not only medicated but also moistened. The volatile oils such as eucalyptol and creosote, or carbolic acid, can all be employed in this way, and have been found effective in many cases of chronic bronchitis and phthisis with much bronchial secretion. The want of fresh air in the inhalation chambers is apt to become more apparent to the patient than the presence of the medicated air, and feelings of suffocation, headache and nausea are sometimes complained of. To facilitate their entrance into the deeper parts of the lung, vapours are sometimes delivered under pressure, by means of inhalers constructed on the principle of the accordion, which can be compressed to any required degree; they are, however, but little used.

The *drugs* best suited for administration by inhalation are the following:—Local astringents for application to the pharynx and larynx may be applied in the form of spray. Such are tannic acid (gr. x-3j), chloride of zinc (gr. ij-3j), lactic

acid (℥xx-3j). Cocaine as a local anæsthetic may be used in spray of a strength of 6 per cent., or even stronger in severe cases.

Stimulant or sedative vapours are best used by means of oro-nasal inhalers or in the simple arrangement lately introduced by an American firm, in which the volatile substance to be inhaled is dropped into a tube, a part of which is packed with coarse pine wood sawdust. This absorbs the fluid, and permits of its slow evaporation, as the patient inhales through the other end of the tube, which is shaped for the purpose. The vapour of chloride of ammonium has been much employed of late years, but chiefly for affections of the posterior nares and Eustachian tubes.

Inhalers are now contrived by which the same act of suction draws the vapour of sal ammoniac and of hydrochloric acid from separate bottles, to meet together in a common receptacle from which the mouthpiece opens. The mixed gas is drawn through water contained in this receptacle, and is capable of further medication by adding any volatile substance to the water.

The volatile oils suitable for use in the moist vapour or steam inhalers, are pinol (℥iij-3j), creosote (℥j-3j), carbonic acid (20 grains to the pint), compound tincture of benzoin (1 drachm to a pint), conium (succus conii, 2 drachms to a pint). Iodoform, iodine or eucalyptol may be employed in small quantities in the simple respirator inhalers, a few drops of the following preparations being used for each inhalation:—R Ol. eucalypti, ʒijss; chloroformi, ℥xxxvj; sp. rect., ʒijss; iodoformi, gr. xv. R Iodi, gr. viijss; ætheris ʒss; ac. carbol., ʒss; creasoti, ʒijss; sp. rect., ʒij. R Ol. eucalypti, alcohol ethylic. aa part. æq.

In using the foregoing substances in the steam draught inhaler, it should be remembered that the more volatile the remedy the more essential is it that it be used directly the steam begins to come off freely. Such substances are apt to be volatilized very early, and hence the steam delivered during the first few minutes is of more importance than all that comes after. This fact is very apt to be forgotten in the routine of practice.

E. CLIFFORD BEALE.

INOCULATION is the introduction into the body of a morbid germ or poison by direct application to the subcutaneous or submucous tissues. It may be accidental or intentional. The *materies morbi*

may be introduced by being applied to an abraded surface or by subcutaneous injection. Some diseases are only communicable by inoculation, such are vaccination and acquired syphilis.

INSANITY.—This term comprises the various symptoms of disorder in the functions of that part of the nervous organization of man which is concerned in the production of the phenomena to which we give the name of "mind."

Insanity may be due to defective development, to acquired disease, or to the natural decay which is the fate of all organic structures.

This subject is of increasing importance, and every medical man must be prepared to deal with insanity in its clinical, social, and legal aspects. The legislature has recognised that insanity is a disease, and has enacted that certificates of insanity shall be given solely by medical men. Moreover, it has recognised that insanity differs from all other diseases in that it snaps the continuity of conscious existence, and creates for the time what for all practical purposes must be considered a new individual, and for the care of this exceptional individualism, the product of disordered brain action, it has passed special laws and overridden the most ancient and sacred rights of citizenship. Having entrusted medical men with such large powers, the State expects that due care shall be exercised, and neglect or ignorance on their part may render them liable to be mulct in damages. For the legal questions which concern him the reader is referred to the article, **LUNACY LAW**; the clinical and social aspects will be here considered.

Symptoms.—Leaving the symptoms of idiocy (*q. v.*) to be considered separately, we find that the first indication of insanity is a change in the character of the individual. Feelings of dulness, sadness, apathy, indifference, perplexity or confusion, or on the other hand a sense of buoyancy, unwonted activity or recklessness may be observed. Such conditions are common to all human beings, but in the case of the patient on the verge of insanity, they come on without due cause, and are totally foreign to his real nature. Thus, the cheerful and energetic may become moody and listless, and the placid restless and hilarious.

The actions soon correspond to the frame of mind, business is neglected, or rashly executed, the personal habits alter,

and the appetite becomes capricious, there is loss of sleep, and often a feeling of ill-health or of impending trouble.

This is the premonitory stage, and if rest and change of scene be provided, the attack may pass off, but will generally advance to well-established mental unsoundness. In the latter case we may find that from the feelings above-mentioned definite delusions have crystallized. For example, the patient may imagine that he has committed theft or murder, or that the venial sins of his youth are rising against him. He may imagine he is ruined, that his children are destined to be injured, or that his wife has turned against him or been unfaithful, or a thousand other ideas may dominate him.

The occurrence of hallucinations will render further progress towards an active form of melancholia easy and rapid. Visions may terrify him at night and voices insinuate the very facts of which he is most afraid. The anxiety about the bodily health may deepen to hypochondriasis, or the victim may fly to drink or seek distraction in objectless travel. The further progress of the case can be readily understood, the patient becomes violent and unmanageable, refuses his food, or threatens murder or suicide.

This is a gradually deepening melancholia, but the case may pursue a very different course. After a melancholic prelude of short duration, symptoms of excitement may supervene, and the further progress of the case is the same as if the first symptoms had been unnatural gaiety and activity. The patient indulges in all sorts of extravagances, spends money freely, takes to drink, becomes perhaps erotic and indecent, and occupies himself with fresh amusements or frivolous pursuits, and becomes quite indifferent to family and business affairs, or propounds the most absurd ideas upon these subjects. Definite delusions of wealth and grandeur, or of suspicion, mysterious agency and persecution may be developed. Many other symptoms will be described elsewhere, but the above will give a sufficient idea for the present of the two chief forms of insanity, melancholia and mania, of which there are many varieties.

The only other type which need be considered in the present connection is dementia or weak-mindedness, which is a factor in all cases of insanity, and is the chief feature in some alcoholic cases, in most cases of general paralysis, and in

all cases of senile and organic brain disease. Dementia is a weakening of the powers of memory, volition, judgment, reasoning, and of the association of ideas, it has been well called "the goal of all the insanities" and is fully described elsewhere. A variety of dementia, namely stupor, is a chief feature in some cases of melancholia, and may vary from mere apathy to catalepsy or a trance-like condition. General paralysis may begin with any of the above symptoms, but its most striking characteristics are the steady progress towards dementia, and the constant association of motor and mental weakness.

It is evident from the above description that insanity does not evolve any new and unnatural powers of mind, but either weakens those already existing, or brings into prominence unused potentialities of the individual brain. Alters the relationships of the various elements of mind, overthrows the balance which has hitherto been maintained, allows full liberty to tendencies which have previously been restrained, gives to the carefully concealed hopes, fears and wishes of a lifetime the reality of facts, and permits the appetites and passions to run riot to the detriment or absolute loss of the established affections.

No absolute distinction can be drawn between insanity and the many forms of temporary mental aberration. In the individual who gives way to overpowering passion, in the victim of hysteria, in the delirium of fever, and in the action upon the brain of alcohol and other tonic agents, we see conditions closely allied to the various forms of insanity. In the phenomena of sleep and of dreaming and in the actions of the hypnotised brain, we see temporary phases of mentalization which closely resemble mental conditions common among the insane. In dreaming, for example, self-control and all relation to time and space are lost, and impossible combinations of incongruous persons, events and opinions seem natural, but the personal identity is quite definite, and the same conditions are often observed in the acute forms of insanity.

Diagnosis.—The elements of diagnosis are a knowledge of the various forms of insanity and practical experience in dealing with the insane. For the guidance of those who have had little experience, some general considerations, sufficient for the establishment of mental unsoundness, are here discussed, but the accurate diagnosis between the various

forms is treated in the special articles dealing with each variety.

In the first place, great caution must be exercised in giving a decided opinion until the case develop, for in no department of medicine will a mistake be more readily discovered, or more deeply resented. Prior to seeing the patient, full information should be obtained as to the previous history, the family history, and the tastes and tendencies of the individual in question, and any changes in these latter must be carefully considered. Before the actual visit a general scheme of questions should be made out, and though each specialist will recommend his own method, it may be useful to suggest the most important subjects.

It is most desirable that the visit should be that of a doctor to a patient and, unless the case be exceptional it is well to have no misunderstanding on this point. It will thus be natural to begin by inquiring about the bodily health. The expression of face, and the condition of the pupils and tongue should be noted, and inquiries made as to the appetite and the relish for food. If any dislike for food exists the reason should be elicited, as hallucinations of smell or taste may exist, or delusions of obstruction to the passage of food, or the patient may believe he is commanded not to touch food, or that it is wrong to take it for various reasons.

It is well also to ask as to the condition of the bowels, and special inquiries about sleep and the existence of dreams are most important. If sleepless, the patient will generally after a time confess the cause. Noises in the ears, or actual voices, flashes of light, or visions, curious feelings about the body, such as electricity, or annoyance by people outside the house may be assigned as the cause, or simply pain in the head, uneasiness, or unhappy trains of thought.

The condition of the patient's dress, and the appearance of the room may afford indications. The domestic relationships may next be touched upon, any change in the affection for wife or children and any undue anxiety for their future noted. The business or profession of the patient will suggest a series of questions, his hopes or fears for the future may be elicited, and questions asked as to his relations with his neighbours. Finally, a few words may be said on the social, political or religious topics of the day, and if the condition of the memory be not already obvious it may be tested by a few simple questions.

At any part of the interview some hesitation, mental confusion, or incoherence may become apparent, or it may become obvious that the patient is concealing something. Slight contradiction or pretended misapprehension may then be necessary to break the slender bonds of self-control. When a hint has been obtained as to the line the mental unsoundness takes, it will often be advantageous not to follow the clue at once, but to recur to it at a later stage, when the patient's mind is occupied with other ideas. It is useful to force from the patient a confession that some change has come over him, to listen to his explanations of the change, and to suggest trivial causes which will be probably resented, and lead him to give full details.

Of course all this trouble may be quite unnecessary, if the patient be excited or violent, or incoherent, or in the condition described as "raving madness" by the older authors, the mere facts observed may be sufficient without a single question, but even here the actual words uttered should be given, and will always add considerably to the strength of a certificate. The possibility that the patient may be under the influence of drink, or of some narcotic or poison, or have been driven to his present condition by ill-usage, should never be lost sight of, but the ordinary knowledge of his profession possessed by every medical man ought to prevent the possibility of this error. It is important also to see some of the patient's recent letters and any bearing upon the mental condition should be kept, as they would form useful evidence if legal troubles should ever arise. The tests for mental capacity sufficient for the disposal of property, will be found in the article on LUNACY LAW (*q.v.*).

Prognosis. — Only general considerations can be mentioned here, and the reader is referred to the special articles on the various forms of insanity. As to age, the younger the patient the better the prognosis, but some adolescents present a strong tendency to secondary dementia. A short duration of the symptoms is decidedly a favourable characteristic, but if the symptoms continue unchanged for a year, the prognosis is bad, though a few cases, especially those of melancholia, recover after an attack of several years' duration. Persistence of hallucinations of hearing or smell, any tendency to periodicity in the symptoms, little disturbance of bodily function originally, or

improvement in bodily health without corresponding mental improvement, the absence of sufficient cause, and a dead stop after recovery up to a certain point, are all of ominous prognostic import.

On the other hand, an adequate cause, acute symptoms with much disturbance of the bodily functions, followed by a gradual convalescence, in which mental and bodily improvement go hand in hand, are all favourable characteristics.

The effect of the presence of neurotic inheritance on the prognosis is twofold: there is strong tendency to recovery, but an equally strong tendency to recurrence of the attacks. When the insanity is simply an exaggeration of previously existing eccentricity, the prognosis is bad, especially if the eccentricity be the result of neurotic inheritance.

Ætiology. — The causes of insanity are divided into predisposing and exciting, but many causes act in both ways.

The chief predisposing cause is neurotic inheritance. As knowledge grows, so does the certainty that we must look to the original constitution of the brain as the first and chief cause of mental breakdown. Not one of the ordinarily assigned causes are in themselves sufficient to bring on insanity. Such causes operate upon all human beings more or less, and it is not the brain which is subjected to the severest or most incessant action of the cause which breaks down, but the brain which is least fit to withstand the attack. Now, what we call neurotic inheritance, undeniably renders the brain more liable to be affected by these various causes, but the belief is becoming more general every day, that whether we can discover the fact of such inheritance or not, its existence, or the existence of a similar constitution of brain, is indisputable. For one man who breaks down mentally under the influence of drink, domestic troubles, or business worry, there are scores who under a precisely similar causation do not break down. The condition common to all mental disturbance is to be sought in inherent and inherited brain defect.

The influence of sex is slight and the excess of female lunatics under treatment is due to the much greater mortality among males, and the shorter period occupied by them in recovery. Some causes press more heavily upon, or affect only the male sex.

The influence of age is marked, the vast majority of the cases of occurring insanity fall between the ages of twenty-five and forty-five, the period of full de-

velopment of body and mind. The number of cases of insanity per 10,000 of population steadily increases to the age of twenty-five, and after forty-five as gradually decreases.

Insanity is much commoner among civilised than among barbarous nations. Poverty, insanitary surroundings, and privation, are all contributing causes. Congenitinity, or great difference in the ages of the parents, accidents during pregnancy, and birth, infantile convulsions, epilepsy, venereal excess, masturbation, nervous shock, the physiological crises of life, puberty, pregnancy, lactation, and the climacteric crisis, may all be mentioned as predisposing causes. But the cause which in its results to the individual and to his descendants ranks next to neurotic inheritance, is unquestionably drink, and it is probable that neurotic tendencies are created both in the individual and in the family by indulgence in alcohol.

Among the exciting causes we find some of those mentioned as predisposing causes, such as drink, epilepsy, pregnancy, and disorders peculiar to women, and to these may be added, injuries to the head, acute bodily diseases, such as fevers, diathetic disorders, such as gout or syphilis, anæmia and diseases of the blood-vessels, and special poisons such as lead.

Treatment.—The details of treatment must be sought elsewhere, only general principles can be discussed here. The cardinal principle is removal from old surroundings, and if this can be effected elsewhere than in asylums the friends will be grateful. But for acute cases, and the majority of all cases, asylum treatment affords the best chance of recovery, and the earlier the friends can be persuaded to take this view the better for the patient. Fresh air, abundance of food, light employment, and plenty of amusement, are main principles. The tonic effect which the indifference of the other patients has upon melancholics, and the absence of elements which attract the attention of the acutely maniacal, are not to be forgotten, and there can be no question that the patient suffers less in conforming to asylum discipline, which affects all alike, than when under surveillance in a private house, or in the home of which he was the active head.

Medicinal treatment is of little avail at first, sedatives should be sparingly used, but are imperative in some cases, and naturally are more frequently necessary in cases in private care than in asylums. Chloral, in the writer's experience, is the

most trustworthy and least harmful of narcotics, and may sometimes be usefully combined with morphia. The latter is useful in some cases of active melancholia, and in mild senile excitement and restlessness, but should be avoided when the excitement is very acute, and where there is any exhaustion, and in cases which refuse food, or in which dyspeptic troubles are present. Hyoscyamine and the hydrobromate of hyoscyne should not be used at all when the patient is young, and should be avoided whenever possible. The former finds its chief use in the restlessness, violence, and destructive habits of the confirmed general paralytic, but should not be given unless the appetite be good. Bromide of potassium, digitalis, henbane, Indian hemp, ergot of rye and Calabar bean have all had their fervent advocates, but with the exception of the first-named are little used. Bromide of potassium has a distinctly bad effect upon some epileptics, apparently it lessens the number of fits, but favours the substitution of acute maniacal outbursts. Paraldehyde is very useful in some cases, but is nauseous and is generally refused by patients, and the same objection applies to hypnone, which is, however, yet upon its trial as a hypodermic remedy. Bromidia is useful as a mild soporific. Urethane appears to be useful, but in somewhat larger doses than at first recommended, and the latest addition to the long list of narcotics, sulphonal, is being tried with favourable results.

Generally speaking, the practitioner will do well to be chary in prescribing narcotics. Chloral is the most generally useful, and acts well hypodermically or by the rectum.

For excitement, when the bodily condition is good, prolonged hot baths and the wet and dry packs are used, but are not free from objection nor from danger. In cases with much excitement combined with bodily prostration, such as in active melancholia, or in puerperal insanity, energetic feeding, if necessary with the aid of the stomach-tube, and the free use of brandy, are absolutely essential. In such cases a few hours' delay may mean an aggravation of the symptoms, or even the death of the patient.

When the acute symptoms subside, general attention to the bodily health, the use of tonics, especially iron and cod-liver oil, is to be commended. If there be a tendency to secondary stupor or dementia, the cold shower-bath and the Russian douche-bath will be found stimulating. The value of electricity and

massage is still an open question. In cases with stupor, hypnotism has lately been given a few trials.

G. T. REVINGTON.

INSANITY, CLASSIFICATION OF.

—This subject is full of difficulties, and while many attempts have been made, we are yet without a satisfactory classification. Various bases have been used for the purposes of classification, and the following may be mentioned, and the names will in each case indicate sufficiently for the present purpose the basis which was used—the somatic, the ætiological, the somato-ætiological, the symptomato-ætiological, the physiological, and the psycho-symptomatological. But in the midst of all this variety, authorities are agreed that there are three main forms of insanity, to which broadly speaking all cases can be reduced, namely, melancholia or depression of brain function, mania or exaltation of brain function, and dementia or weak-mindedness, which includes amentia or congenital weak-mindedness, and the acquired weak-mindedness of adults.

Even general paralysis and epilepsy can be included, for while maniacal and melancholic symptoms are common in these diseases, the most striking characteristic of both is the inevitable progress towards dementia.

In the writer's opinion another form should be added, delusional insanity, in which, although there is frequently no marked depression nor exaltation of brain function and the dementia which is always present may remain for years only a slight factor, there is definite distortion of brain function, as shown in the fixed and often outrageous delusions which exist, in spite of fair reasoning power and judgment, upon topics other than the subject of the delusions.

But having recognized these primary forms, what shall be the basis for subdivision, what system of nomenclature will express and convey most information? In the writer's opinion a classification according to the period of life will incontestably be found the most practically useful. To describe a case as adolescent stupor or puerperal mania will ever be a description satisfying as to symptoms, and useful as to treatment. The character of the symptoms and the mode of treatment turn far more upon the stage to which the development of brain and body has attained than upon any other factor in the case.

The following is an arrangement which seems to answer all the requirements of a scientific classification:—

- | | | |
|---|---|---|
| The four primary forms of mental unsoundness. | { | 1. Melancholia (depression of brain function). |
| | | 2. Mania (exaltation of brain function). |
| | | 3. Delusional insanity (distortion of brain function). |
| | | 4. Dementia (weak-mindedness—"the goal of all the insanities"—including amentia or congenital weak-mindedness). |

Scheme of Classification according to the Period of Life at which the Disease appears.

- | | | |
|---------------------------------------|---|---|
| Insanities of infancy. | { | Imbecility, idiocy. |
| Insanities of childhood. | | Mania, melancholia, moral insanity, epileptic insanity. |
| Insanities of adolescence. | { | Mania, melancholia, insanity of stupor, epileptic and hysterical insanity, sexual hypochondriasis. |
| Insanities of maturity. | | Mania, melancholia, puerperal and lactational insanities, delusional insanity, alcoholic insanity, general paralysis. |
| Insanities of the climacteric period. | { | Mania, melancholia, delusional insanity, visceral hypochondriasis. |
| Insanities of decay. | | Mania, melancholia. { With dementia as a prominent characteristic, and probable conclusion. |

G. T. REVINGTON.

INTESTINAL OBSTRUCTION.

—This term is generally limited to cases in which there is complete obstruction to the passage of the contents of the bowels, solid, fluid and gaseous, the state of merely imperfect evacuation of these contents being regarded as "constipation."

This distinction is however, by no means absolute, since the causes which may eventually operate to produce complete obstruction frequently, in their earlier manifestations, exhibit merely the symptoms of irregular constipation. Again, owing to the variety of the conditions which lead to obstruction, in addition to the cardinal symptom of complete constipation, there are often concomitant symptoms varying in severity and in their relative predominance.

In some cases, where the health has been previously good, and the intestinal functions regularly performed, the symptoms of obstructions set in almost suddenly, with or without some exciting cause, such as a strain or injury, and rapidly become urgent. Such cases are

generally denoted by the term *acute*. In other cases the absolute arrest of the normal evacuation is more gradual, and is preceded by a period of imperfect or irregular performance of this function continued over a longer or shorter time. Such are the *chronic* cases.

The use of these terms is however only to be regarded as a matter of clinical convenience. They by no means imply that the underlying anatomical condition is in the one case recent or acute, in the other of long standing or chronic. For although in many cases it may be true that the condition giving rise to sudden and urgent symptoms is itself suddenly developed (*e.g.*, impaction of a gall-stone, or an intussusception), yet there is frequently no sort of parallelism between the clinical course and the anatomical state. For a condition of long standing may either directly or indirectly be first revealed by the onset of acute symptoms, and yet in other cases the same condition will have a clinical history more in accordance with what is known of its nature and probable duration.

With this caution, which will receive abundant illustration hereafter, it will be most convenient to introduce this subject by considering generally the symptomatology of the acute and chronic types.

ACUTE OBSTRUCTION occurs, as its name implies, with suddenness.

Symptoms.—The patient may have been previously in good health, may have never had any symptoms of derangement of the bowels, when he is seized with a severe attack of griping pain in the belly. On inquiry it may not be possible to attribute this attack to any antecedent circumstance, such as indiscretion in diet, injury or strain, although in a certain number of cases such assumed exciting causes do exist. The pain may be very severe indeed, and it is usually referred to the region of the umbilicus, no matter where the seat of the obstruction may be. It is mostly followed speedily, or after a few hours' interval, by vomiting. From the onset there is no action of the bowels, not even the passage of flatus, and this notwithstanding that the occlusion may be high up in the intestine.

From this it would appear that owing to the sudden mechanical interference with its normal action the bowel below the seat of obstruction becomes quite paralysed, although it may be possible to produce an evacuation of the contents of the colon by means of enemata.

Urgent symptoms of obstruction may be induced (by reflex paralysis?) by sudden mechanical irritation of the intestinal nerves, without there being any actual obstruction—*e.g.*, acute strangulation of omentum, or of one wall of the gut.

The vomited matters at first consist of the gastric contents, but soon become bilious or duodenal, and have a greenish or bright yellow colour. The act of vomiting is excited whenever food is taken, but after a time it tends to recur independently of taking food. Within a variable period, seldom more than three or four days, the vomited matters become obviously stercoraceous. It is generally considered that the *early* occurrence of vomiting indicates that the seat of obstruction is situated high up in the small intestine, but this is not a safe diagnostic rule, since the same fact may be observed whenever the obstructing cause is such as to severely strangle the bowel. Associated with this symptom, and in a measure dependent upon it, there may be great thirst, and also a marked diminution in the amount of urine passed, perhaps even suppression.

The belly is more or less distended, the degree of this distension depending both on the situation of the obstruction and on the duration of the symptoms. It is comparatively rare in acute cases for the individual coils of distended intestine to be visible through the parietes, although there are many exceptions to this, and the presence of visible peristalsis cannot be held to exclude an acute case. The distension, as a rule, is fairly uniform, but may exhibit a certain want of bilateral symmetry.

On palpation, there is tenderness, which usually develops a short time after the pain, but it is seldom so definitely localized as to be a trustworthy guide to the site of the obstruction. In some forms a tumour may be plainly felt, through the abdominal parietes (*e.g.*, intussusception) or on rectal examination, or else the latter only reveals the swelling formed by the coils filling the pelvis. To percussion the abdomen is in all parts tympanitic.

The patient rapidly becomes exhausted by the pain and incessant vomiting, the features become pinched, the pulse small, perhaps thready, the respirations shallow and rapid, and the temperature subnormal. There is no impairment of intelligence, but the condition is that of collapse, and death follows.

CHRONIC OBSTRUCTION has a different clinical history. In it the patient has

probably suffered for months or years from irregular action of the bowels, he has been either habitually constipated, requiring frequent recourse to purgatives, or has been subject to attacks of constipation alternating with diarrhoea, the latter probably being really excited by the former. At any rate there is in his previous history sufficient to point to the final complete obstruction being only the necessary sequence of deranged action of the intestine of long standing. Sometimes, but not invariably, he may have noticed that the tendency to constipation has gone on increasing with the lapse of time, and, perhaps, that the motions have become more scanty in amount or smaller in size. Then comes a time when the bowels no longer respond to the measures on which reliance has hitherto been placed for their relief, and perhaps stronger purgatives are tried with a like negative result, except the production of more or less severe griping pain. It may be learnt too that there has been of late a greater liability to attacks of "colic" than hitherto. Enemata also fail to procure the desired relief. After some days of absolute constipation, when even flatus does not pass, the abdomen becomes more and more distended and the true nature of the case is revealed. Now at length vomiting may set in, and, in time, become stercoraceous. The patient sinks into a state of collapse, in which he may die.

Differential Diagnosis of Acute from Chronic Obstruction.—Amongst the symptoms and signs which characterize the chronic cases as distinguished from the acute are, the comparatively greater amount of urine excreted, the visibility of the distended coils, which may be often seen in peristaltic movement (due to the hypertrophy of the muscular coat of the bowel above the obstruction?) and perhaps the presence of tenderness and fulness over the cæcum. There are other signs which may occur more frequently in this form, and which depend on the site of the obstructing cause, to which reference will be made in speaking of the diagnosis of the seat of obstruction.

There is one sign yielded by examination of the urine, which, though not pathognomonic, is yet very constant in intestinal obstruction, being, in the experience of the writer, far better marked in acute than in chronic cases. This is the presence of indican (or its derivatives) in the urine, which may be ascertained by gently adding to it some

hydrochloric acid in the cold. At the line of junction of the two fluids there will appear a violet or dark bluish-black band, the tint being deeper in proportion to the amount of the "indican" present. In a case recently under the care of the writer, this test, which was well marked during the symptoms of obstruction, disappeared after the obstruction (a band) had been relieved by operation. The presence of indicanuria in such cases may perhaps be due to the absorption of indol retained in the bowel with other faecal products or possibly in part to the nervous disturbance in the abdomen caused by the attack.

The Diagnosis of the Seat of the Obstruction is by no means easy. There are, it is true, certain rules (not wholly without exception) which may be usefully applied to distinguish between obstruction situated in the large and the small intestine, but beyond this rather wide limit it is often impossible to go.

The seat of pain or tenderness, which, as stated, is generally localized about the region of the umbilicus (probably because of the contiguity to the solar plexus, where the painful impression may be referred), is not to be relied on. The very early onset of vomiting may be taken to indicate not only that the case is acute but that the obstruction is high up in the intestine.

The obstruction may be inferred to be in the *small* intestine, when, (1) the abdominal distension is most marked anteriorly, the flanks being comparatively flattened; (2) large quantities of water can be readily injected into the bowel through a long tube introduced into the rectum, and when it can be proved by auscultation that the fluid passes into the cæcum; (3) indican is present in the urine in considerable quantity. The fact that in cases of obstruction of the small intestine there is great diminution in the amount of urine passed is probably allied to the severe and prolonged vomiting which so often characterizes this form, and cannot therefore be considered as a fact of much diagnostic value.

On the other hand the obstruction is probably seated in the *large* intestine if there be (1) marked general distension, and especially fulness of the flanks, of both flanks if the obstruction be in the rectum or sigmoid, of the right more than the left if it be in the splenic or hepatic flexure; (2) failure to inject much water or to detect evidence of its passage into the cæcum; (3) an obstruction detected in or outside the rectum

on digital examination. This is of course obvious. In the case of obstruction higher up some aid might possibly be gained by the attempt to pass a long bougie into the colon, a proceeding which may, however, lead to a fallacy from the difficulty often experienced in passing the instrument through the sigmoid flexure. At one time much value was attached to the introduction of the whole hand and arm into the bowel, but this procedure requires some skill as well as the possession of a small hand by the operator. It is not practised now to any extent.

The **Diagnosis of Intestinal Obstruction in General** has in the acute cases to be made mainly from *acute peritonitis*, especially when the latter is dependent on perforation. In some cases, indeed, the distinction between these two conditions is well-nigh impossible, for in the history of the attack, the mode of onset, the occurrence of pain and vomiting, there may be no distinctive feature of the one over the other. Since, however, the causes of such perforative peritonitis (exclusive of typhoid ulceration) are practically limited to perforation of the appendix or of a gastric or duodenal ulcer it may be possible by careful exclusion of these conditions to make a diagnosis. It is, however, here that the value of laparotomy as an exploratory operation is seen, a procedure which will be also available for the treatment of the case.

In acute peritonitis there is usually more general pain and exquisite tenderness of the abdomen than occurs in simple acute obstruction; the patient lies on the back with the knees raised; the signs of collapse are marked, especially the quick small pulse, and usually there is some rise in temperature. Moreover, since peritonitis is rarely idiopathic, every care should be taken to discover whether there be any assignable cause for its occurrence.

In *chronic* cases the diagnosis rests between permanent obstruction or constipation, and here the effects of repeated and large enemata are of great service. It is seldom that constipation *per se* leads to complete obstruction, but this sometimes does happen, and in that case there is no need of the distinction here drawn, at least for general diagnosis.

VARIETIES OF INTESTINAL OBSTRUCTION.—There are several ways of classifying the various causes of obstruction. Mention has been already made of the division into acute, and chronic, examples of which are to be found in both the

small and large bowel, but perhaps in the former the acute cases preponderate, in the latter the chronic. Or the conditions may be considered in reference to the part of the intestine in which they commonly occur. Or the division may have reference to the relation of the obstructing cause to the tube which is thereby occluded, as causes operating within the intestine, in its walls and outside the canal. The order in which they are discussed here is framed rather on their anatomical and pathological affinities.

1. Occlusion by faecal accumulations, concretions, gall-stones, foreign bodies.

2. Obstruction from strangulation of the intestine, as in hernia and by bands.

3. Obstruction from malposition of the intestines as in volvulus and intussusception.

4. Obstruction by compression and traction.

5. Strictures, congenital, cicatricial or cancerous.

6. Tumours within the intestine.

Class I.—FÆCAL ACCUMULATION, GALL-STONES, &c.—Fæcal Accumulation.—This, which may be the outcome of habitual constipation, depends for its supervention upon atony of the colon, where the chief accumulation takes place. The more or less paralysed bowel may become greatly dilated and enormously distended with fæces, which are hardened and fixed. Sometimes the mass can be readily felt through the parietes, and under a prolonged and patient course of enemata, aided, if need be, by mechanical dislodgment of the contents of the rectum, the mass may be observed to gradually lessen.

The prognosis in such cases is rarely grave, but there is always a liability to recurrence, if the evacuation of the bowels be neglected. Indeed, in some cases this form of obstruction has proved fatal, and has been mistaken for a stricture of the colon, which it simulates in its course. The operation of colotomy has been done on this mistaken diagnosis.

Impacted Gall-stone.—The seat of impaction of a gall-stone in the intestine is likely to be the ileum, since the larger calibre of the duodenum and jejunum admits of the passage of a stone which could not pass through the ileum. The occurrence is mostly due to the escape of a gall-stone of large size into the bowel by ulceration from the gall-bladder, rather than from the duct, into which it is rare for stones large enough

to occlude intestine to pass. The onset of symptoms of obstruction is sudden, the pain severe, and vomiting urgent. There may have been a history of former attacks of biliary colic and jaundice, but it is possible that no such events have occurred, in which case a material aid to a correct diagnosis will be wanting. The patient may have suffered for some time previously from a pain in the hypochondrium, and it is possible that the existence of a tumour in the site of the gall-bladder may have given rise to the suspicion of the presence of a gall-stone before the onset of intestinal symptoms, which mark its escape into, and lodgment in, the bowel. Unless, however, there have been previous colic and jaundice, such a diagnosis would not be justified.

Enteroliths formed of matted hairs that have been swallowed, or of semi-calcified masses, as from insoluble salts of lime, magnesia, or bismuth, and all manner of *foreign bodies* swallowed accidentally or intentionally may come to block the bowel. Cruveilhier gives a drawing of a cecum filled with cherry-stones, and a similar case was under the care of Sir W. Jenner in University College Hospital some years ago. In that case the collection of stones could be felt during life. Obstruction has also been caused by a collection of lumbricoid worms.

Class 2.—INTERNAL STRANGULATION.

—One-fourth of the total number of cases of intestinal obstruction from all causes, (excluding hernia and affections of the rectum) are due to internal strangulation according to Treves.* This statement can be substantiated by the comparatively small experience of any individual hospital physician. The mode in which the strangulation is effected is very varied, and only some of the more common varieties will here be mentioned.

(1) **Strangulation through apertures**, as hernia through the foramen of Winslow, obturator hernia, retro-peritoneal hernia, or the passage of a loop of intestine through a rent in the omentum or mesentery, and the constriction of the gut, partly by the latter, partly from the weight of the bowel causing it to be sharply bent over the margin of the aperture.

* "Intestinal Obstruction," London, 1884. For fulness of detail and scientific study of the subject there is no work equal to this admirable monograph.

(2) **Strangulation by Bands.**—

These are the most common, and the "bands" may be formed in a variety of ways. Some are formed by old peritonitic adhesions, and in such cases there may be a previous history of localized peritonitis. Or a loop may be caused by the adhesion of the vermiform appendix to the parietes, to a neighbouring part of intestine or Fallopian tube or other viscus. Or the band may be formed by the adhesion of one of the appendices epiploicæ to another, or to the appendix, or elsewhere; the epiploic appendage becoming more or less elongated and cord-like. Or the omentum, from previous peritonitis, may have become adherent, forming a loop through which coils of intestine may pass (a condition liable to ensue after hernia).* Or finally, and this forms a comparatively large class, the constricting band may be formed by a Meckel's diverticulum, which has either retained its attachment at the umbilicus, or, what is more frequent, has become adherent to bowel or parietal peritoneum. The obliterated vessels passing from the region of the bladder to the umbilicus may similarly form constricting cords.

In these and other ways a cord-like loop is formed, through which a portion of intestine, generally as a single loop, may pass and become constricted. Hence in nearly all these cases it is the small intestine that is strangulated, and the onset of symptoms is acute. Where it is possible to obtain a clear history of a previous attack of peritonitis (or of a herniotomy) the diagnosis may be aided, but such evidence is frequently wanting. As a rule the constriction is solitary, but now and then the bowel will be found to be strangulated at more than one spot. The effect of the constriction is to cause great distension of the gut above it, and the collapse of all the coils below. As pointed out by Dr. Kingston Fowler, these collapsed coils tend to fall into the pelvis, where they may be felt on rectal or vaginal examination, and discovered on abdominal section.

Treves points out that strangulation

* Several cases are recorded of intestinal obstruction following ovariectomy, some of which fall under this category, being due to the formation of peritonitic adhesions and loops. This operation is also sometimes followed by a condition of paralytic distension of the bowels, which is relieved by saline purgatives, or by the passage of the long tube.

by bands is more common in males than females, but that in the case of peritonitic adhesions the numbers are about equal, the greater frequency of pelvic peritonitis in the female sex being balanced by the predominance of typhlitis in the male. The latter fact also explains why strangulation due to an adherent vermiform appendix occurs more often in the male.

The same authority states that this form of intestinal obstruction mainly occurs between the ages of twenty and forty. These cases have been termed "internal hernia," and of course in dealing with them care must be taken to examine all the sites of hernia, before arriving at the conclusion that the obstructing cause is within the abdomen.

Class 3.—MALPOSITION OF INTESTINES.—Under this head may be included the conditions of (1) Volvulus and (2) Intussusception.

(1) **Volvulus.**—By this is meant the twisting of the bowel upon itself to such an extent as to completely occlude its canal. The twisting may involve the small or large intestine, the latter being perhaps the more frequent. In order for it to take place, it is requisite that the bowel should be furnished with a long mesentery, as is sometimes the case with the descending colon or the sigmoid. The occurrence of volvulus may sometimes be referred to an injury or unusual effort on the part of the patient. When it happens, the symptoms are mostly acute, and referable to obstruction of the large bowel. The effect of a volvulus upon the intestine itself is similar to that produced by strangulation, but of course if the colon be the seat of the accident there will be much greater distension than in the case of involvement of the ileum.

(2) **Intussusception** or invagination is a frequent cause of obstruction, especially in the young. In this condition a segment of bowel becomes invaginated into the portion next below it, thus forming a cylindrical tumour of variable length. The determining cause of the condition is no doubt undue peristalsis, which may have been excited by some irritation of the bowel.* Thus it

happens in the course of catarrhal enteritis, or it is associated with a tumour projecting into the interior of the bowel from its wall. But it is not always possible to refer the attack to any marked antecedent, such as the occurrence of attacks of colic, which would indicate that the bowel contained some material which it was endeavouring to get rid of by violent peristaltic movement. Thus the presence of a lumbricoid worm may favour the occurrence of intussusception, or of indigestible articles of food or other foreign body.

The site of intussusception varies, and certain varieties may be enumerated depending on this fact, viz. :—

(a) *Ileo-cæcal*, where the invagination begins with the descent of the ileo-cæcal valve into the cæcum and colon, so that the intussusceptum is formed by the ileum as well as by the cæcum and ascending colon, according to the extent of the invagination. This is the most common variety, and is occasionally of such extent that the ileo-cæcal valve may be felt per rectum.

(b) *Colic*.—In this variety the invagination is limited to the large intestine, as of the ascending into the transverse portion, or of the latter into the descending colon.

(c) *Neal*.—Here the ileum is alone concerned. It forms a typical instance of the condition.

(d) *Ileo-colic*.—This variety is characterized by the prolapse of the ileum through the lips of the ileo-cæcal valve. It is rare, and must be clearly distinguished from the ileo-cæcal variety.

The mere fact of the occurrence of intussusception does not suffice to cause obstruction. It is possible for the passage through the invaginated portion to be still pervious, and the condition may in such circumstance become chronic, and not be marked by the urgent symptoms usually present. For in the majority of cases the invagination is productive of constriction of the invaginated portion at the point where this becomes continuous with the ensheathing portion. In consequence of this there is an impediment to the return of blood from the included bowel and its mesentery, so that these become swollen, and thus increase the liability to complete constriction. The intussusceptum becomes intensely congested, and its vessels on the mucous membrane may rupture, filling the interior with blood clot. Then, owing to the strangulation, a process of necrotic softening takes place, inflamma-

* The condition is sometimes met with, especially in the young, on post-mortem examination, without any symptoms of its occurrence during life. The appearances in such cases denote that the invagination (which is often multiple) occurred just before death.

tion is set up between the contiguous serous coats of the two portions of bowel, which thus become adherent. After a time the detachment of the intussusceptum is effected by sloughing (provided that the patient survive so long), and it may come away entirely, and thus naturally restore the continuity of the bowel. The circular ulceration which remains may subsequently cicatrize.

Such spontaneous recovery is, however, rare, the case often terminating fatally from exhaustion due to the obstruction, and to the effects of blood-poisoning from the gangrenous intestine. It must not be supposed, however, that intussusception, unrelieved by art, will invariably run this serious course. There can be little doubt that occasionally the condition may occur and be spontaneously reduced after an interval of a certain time, or very shortly after the occurrence of the intussusception, without any serious symptoms having been set up, whilst, as remarked, the condition may sometimes be more or less chronic, and may have existed a long time before any obstruction is produced.

Symptoms.—The occurrence of intussusception is marked by much pain in the belly, by tenesmus, and perhaps some diarrhoea, and by vomiting and anxiety. There may in a few hours be some melæna (an important indication), which lasts only a short time, that is, so long as there is extreme congestion of the invaginated segment, a condition which precedes complete stasis. The detection of a tumour on palpation of the abdomen, for which it is often necessary to administer an anæsthetic, is however the chief diagnostic sign. This is of a smooth cylindrical or sausage shape, and usually lies in the position of the ascending colon, or even in that of the transverse colon. It may even be wholly on the left side of the abdomen, and its lower extremity be felt per rectum. In some cases the tumour may be observed to shift its position as the intussusception continues to increase.

The *diagnosis* has to be made from other forms of acute obstruction; and the history of melæna and the presence of the characteristic tumour render this comparatively easy. It has further to be distinguished from a fæcal tumour, but it is only in the chronic and milder cases that this mistake is likely to occur. Between phyllitis and intussusception the diagnosis may be more difficult, but here the suddenness with which the swelling

appears, as well as the melæna, mostly suffice to point to the latter.

Class 4.—COMPRESSION, TRACTION AND KINKING.—Obstruction may be brought about by the more or less general matting of the intestines by peritonitis, as in general or local chronic peritonitis, tubercular or otherwise. The adherent coils unable to exert their natural peristalsis tend to become filled with faeces. In such cases there is a more or less prolonged history of abdominal symptoms before the onset of signs of obstruction. The cases therefore fall mainly under the "chronic" class, where complete obstruction is preceded by obstinate constipation, and often by attacks of colic. The adhesions may be limited to a few loops only, as when they result from localised peritonitis in the vicinity of the cæcum or the pelvic organs.

In obstruction from tumours external to the bowel, the rectum is chiefly involved. The condition is far more often met with in females than males. The commonest cause is the pressure due to an enlarged uterus or a fibroid tumour arising from the uterus or even retroflexion of this organ, the unyielding walls of the pelvic cavity compelling the flattening of the bowel. The diagnosis is readily made on rectal and vaginal examination.

The condition of "traction" pointed out by Mr. Treves is rare. It has been chiefly observed in connection with an adherent diverticulum which drags on the ileum and eventually produces its occlusion. This also is marked by chronic symptoms.

An analogous state is that described as "kinking," where, owing to adhesion of the small intestine at one spot, the bowel (generally the ileum) becomes acutely bent on itself. The writer has seen this produced by a contraction of the mesentery, the result of old inflammation of the mesenteric glands, which had become cretified at this spot. The patient had had previous attacks of the same kind, in which obstruction had lasted for some days and had then been spontaneously relieved. On the occurrence of a second attack the symptoms were more severe, and laparotomy was performed. It was found necessary to resect the portion of gut at the site of the kink. The case proved fatal.

Class 5.—STRICTURES.—The intestine may be completely occluded at birth by the non-union of the hind gut and anus. This condition of so-called "imperforate anus" or "atresia ani," finds a counter-

part in the duodenum, where occasionally a similar entire dissection of the continuity of the canal is exhibited as a congenital malformation. But short of complete occlusion strictures of the small intestine which are manifestly of congenital origin, are occasionally met with.

Symptoms.—The subjects of this form of malformation may pass through the early years of life without any apparent discomfort, but as age advances and the narrow passage of the strictured portion becomes more disproportioned to the calibre of the rest of the tube, there may gradually arise symptoms of intestinal difficulty culminating in complete obstruction. It will be generally observed in such cases that the abdomen becomes more distended in its central portions, and that the coils of intestine above the stricture become evident through the parietes, showing frequently their peristaltic movement. Such a chronic history and course of symptoms in a comparatively young subject may direct suspicion to this malformation, but the diagnosis is purely conjectural.

Of acquired strictures by far the most common are those which are due to **Malignant Growths of the Intestine** (mostly epitheliomatous). These strictures occur in later life, more commonly in males than in females, and are produced by the contraction of a growth which, arising in one part of the bowel, may come to entirely surround it, and by its destruction form the typical "annular ulcer." In the vast majority of cases these strictures are to be found in the large intestine, and (excluding the rectum) at the flexures of the colon far more often than in other parts. In frequency they occur more in the sigmoid than in the splenic flexure, and more in the splenic than in the hepatic flexure.

Symptoms.—The history of such cases is essentially a chronic one. It is difficult to determine when the stricture commenced to cause any definite symptoms, so insidious is their onset. Sometimes indeed there is no suspicion of any grave trouble until the signs of obstruction set in almost acutely. As a rule the patient may have been subject to habitual constipation for some time, alternating perhaps with "diarrhoea" attributable to the presence of accumulated faeces. He may also have experienced an increasing liability to attacks of colic, especially after taking purgative medicines. Then the abdomen will become more distended and voluminous, there

may be aching pain and tenderness over the caecum, which is especially liable to become distended and even ulcerated, whilst owing to the long duration of the obstruction, the coils of intestine may become plainly visible. During an attack of colic peristalsis may be visible. Vomiting is a late event; it may not even occur at all. On the other hand, these cases may be characterized by recurrent attacks of copious faecal vomiting, with intervals of comparative comfort.

Diagnosis.—With such a history, the determination that the seat of the obstruction is in the colon, together with the age of the patient, justify the conclusion that the case is one of this nature. The condition most likely to be mistaken for it is that of chronic constipation with atony and dilatation of the colon.

It may perhaps be here pointed out that in no case should rectal examination be neglected, since of all seats of stricture, especially malignant and syphilitic, this part of the tract is the most frequently involved. Nor must a history of diarrhoea be allowed to set aside this necessity, for the very presence of such disease may create an irritable condition of the mucous membrane, and a constant desire to defaecate. Tenesmus and occasional melæna are further common signs of rectal disease.

Of other forms of stricture due to previous ulceration it must suffice to give a mere enumeration, so rarely do they occur. Such, for instance, are strictures following tubercular or syphilitic ulceration of the bowel or following the spontaneous detachment of an intussuscepted portion of intestine. Dysenteric and even typhoidal ulcers have very rarely been known to lead to stricture.

6. TUMOURS WITHIN THE INTESTINE.

—Obstruction may be also caused by the gradual filling up of the lumen of the intestine by new growths arising in its wall. Here again cancerous tumours are the most common, and they are perhaps more frequent at the ileo-caecal valve than elsewhere. Some growths indeed tend rather to dilate the bowel than to contract it as pointed out by the late Dr. Moxon. Amongst the rarer kinds of tumour are fibromata and lipomata, which may come to cause mechanical obstruction; various forms of polypoid growth, fibro-myxomatous or other, may possibly be so abundant or so large as to produce a like result. Similar in effect and in clinical characters are cases of chronic intussusception.

The *diagnosis* has to be made chiefly

from faecal tumours when the intestinal condition is apparent to palpation. The obstruction is generally of long standing.

The differential diagnosis of the foregoing conditions must be based upon the consideration of several points in addition to those which are more or less characteristic of the particular form of obstruction, the acuteness or otherwise of the symptoms and the determination of the site of the occlusion. It must be borne in mind that several of the conditions named take their origin in the presence of the relics of pre-existing peritoneal inflammation, mesenteric disease or hernia, and a full inquiry into the previous history of the patient may thus sometimes be of much service. Thus, a history of abdominal symptoms in early life, or of pelvic or caecal inflammation may shed light upon the long subsequent occurrence of symptoms of intestinal obstruction and especially of cases of strangulation. Then again the sex and age of the patient may point in favour of one rather than another form of obstruction. It may be stated almost aphoristically that intussusception is an affection of childhood, strangulation of early adult life, stricture of the colon of advanced life, although there are, of course, exceptions in the case of each of these. If congenital malformation be suspected then search may be made for any other congenital defects, since such errors of development often occur together. These and like considerations may aid in arriving at a conclusion, but it is often impossible to determine, especially in acute cases, the precise nature of the lesion without actual inspection, after exploratory laparotomy.

The Treatment of Intestinal Obstruction must necessarily vary with its cause, but there are certain general principles and methods that are applicable in the majority of cases.

In the first place the administration of purgatives must be absolutely deprecated; much pain, and no good, if not positive harm, may follow their employment. It is, however, incumbent, both as a matter of diagnosis and treatment, to have recourse to copious enemata. For if the condition be merely one of faecal accumulation, perseverance in this course may be rewarded by the removal of the obstruction. It is, however, unwise to continue these attempts too long, and often the severity of the symptoms and exhaustion of the patient will point to their inutilty.

The administration of opium is valuable in allaying pain and controlling peristalsis

and vomiting, but for these very reasons it is unadvisable to prolong its use, lest the urgency of the symptoms be masked, and the time at which there is reasonable hope of relief by operation be overpassed. At the same time the treatment by opiates, combined with low diet, has been advocated as all-sufficient for the cure of many severe cases which in other hands would most certainly have been submitted to operation. It ought to be clearly understood that if the opium treatment be relied on it must not be abandoned in favour of operation at a late stage and when the patient is in a state of extreme exhaustion. In this way the latter procedure has indeed but slight chance of saving the patient, and it seems unscientific as well as wrong to suffer such exhaustion to occur, if the case be seen early enough to anticipate its appearance by speedy resort to operation. This at least is the view of the writer, and although unfortunately but few cases of acute internal strangulation recover, even after laparotomy and the division of the constricting band, it is not possible, in face of the known pathological conditions to refrain from advising an early recourse to this interference as affording the best chance of recovery in an otherwise almost necessarily fatal disease.

But there are less severe measures than abdominal section, which in certain cases may be tried before resorting to it, provided that the patient's strength admit of the delay that they occasion. One of these is free lavage of the stomach. Cases have been recorded, especially in Germany and France, where this simple procedure, frequently repeated, has been followed by the disappearance of the symptoms of obstruction. The writer has adopted the plan in one or two cases, but only as a preliminary to laparotomy, where the faecal vomiting was frequent and distressing, and believes that it is of great advantage in cleansing the stomach of its foul contents, thereby removing one cause of the depression of the vital powers, but that the measure *per se* could effect the liberation of a strangulated bowel is difficult to conceive. There is also a procedure advocated by Mr. Hutchinson, which he terms "taxis," that may be tried for internal hernia as for external, and abandoned in favour of surgical interference if it fail in its object. The method is best described in Mr. Hutchinson's own words:—"The first point in abdominal taxis is the full use of an anæsthetic, so as to obliterate all muscular resistance. Next (the

bowels and bladder being supposed to be empty) the surgeon will forcibly and repeatedly knead the abdomen, pressing its contents vigorously upwards, downwards, and from side to side. The patient is now to be turned on his abdomen, and in this position to be held up by four strong men, and shaken backwards and forwards. This done the trunk is to be held feet uppermost and shaking again practised directly upwards and downwards. Whilst in this inverted position copious enemata are to be given. The whole proceedings are to be carried out in a bonâ fide and energetic manner. It is not to be the name of taxis, but the reality; and great perseverance is to be exercised. The inversion of the body, and succussion in this position, is on no account to be omitted, for it is possibly the most important of all" (*Archives of Surgery*, July 1889, No. I, p. 6). It may be conceded that such a procedure can untwist a volvulus, or indeed enable a loop of intestine to escape from a lax band, and Mr. Hutchinson has been fortunate in the successful issue of some apparently severe cases. Yet the very energetic character of the procedure must, if it fail, materially exhaust the patient, and render him unfit for the severer measure of laparotomy. Thus, in the treatment of internal strangulation we seem to be on the horns of a dilemma, and one can hardly avoid the conclusion that as soon as the diagnosis is made (the sooner the better) the division of the constricting band should be attempted. As regards the operation itself, it may be mentioned that the point before alluded to as first shown by Dr. Fowler,* that the collapsed coils tend to drop into the pelvis, is of much practical value, as enabling the surgeon to find his way to the seat of constriction more rapidly than if he attempted to do so by tracing the distended bowel first in one direction and then in another. Any plan whereby the duration of the operation can be lessened must be welcomed. The possibility of there being more than one constricting band (although rare) should always be borne in mind.

So far we have spoken chiefly of cases of acute obstruction by strangulation. There are, however, in other forms of obstruction, such, for example, as intussusception and stricture, other lines

of procedure. In the former, when the diagnosis has been verified by the discovery of the characteristic tumour (under chloroform if necessary), attempts to effect reduction should be made by the injection of air or water into the rectum. The earlier period at which recourse is had to these measures after the onset of symptoms the more likely are they to succeed. If they fail, then there are two courses open, either to invoke surgical aid to reduce the invagination after laparotomy (and in some cases this has proved very successful, in others it has been found impossible to effect the reduction) or to administer opium freely and trust to the natural process of separation of the invaginated bowel, supporting the patient by nutrient enemata, suppositories, and stimulants, as well as may be, during the prolonged period that must ensue before the spontaneous detachment is effected. Needless to say that in many instances the strength of the patient has given way before what may be termed the "natural" cure could be completed. In the case of an annular stricture of the colon the usual procedure recommended is the performance of colotomy. If the diagnosis be that the stricture is seated in the sigmoid flexure, then the operation may be performed on the left side, but in all other cases it should be a right colotomy, not only because of the uncertainty as to the exact site of the stricture and the avoidance of the risk of cutting down upon collapsed bowel, but also because in cases of long-standing accumulation the cæcum often suffers from the distension, and its relief is more certainly obtained by that operation. Surgery has advanced beyond this merely palliative measure, and cases of successful colectomy have been recorded, the limitation of the disease in the bowel favouring such an expedient.

For the relief of extreme flatulent distension, especially in cases of obstruction of the large intestine, it is sometimes advisable, and even necessary, to puncture the distended gut. This should be done with a very fine trocar (the needle of a hypodermic syringe would suffice), and the gas allowed to escape. The procedure only affords a temporary relief, and is likely to be followed by colicky pain, due to the peristalsis of the bowel being excited by the relief of the distension. It is well, therefore, to give opium when the puncture is made. It may happen that the removal of the tympanites will also be followed by the

* N.B.—Mr. Hulke had independently noted the importance of searching for collapsed bowel.—Ed.

passage of feces through the obstruction, owing to the stricture being relieved from undue pressure above. The procedure is not in all cases free from risk, since the dilated intestine may not be enabled to contract, and so close the opening, in which case there will be fecal extravasation and peritonitis.

In all cases the amount of food administered to the patient should be very small and concentrated, consisting of milk, meat essence in small quantities, or, if vomiting be persistent, rectal feeding must be resorted to. In the less severe cases, where after a few days the obstruction is spontaneously relieved, the diet must continue to be carefully controlled. In such cases also, belladonna will be found of greater service than opium. SIDNEY COUPLAND.

INTESTINES, TUBERCULAR DISEASE OF.—The intestines are seldom, in the adult, the primary seat of tuberculosis, but they are affected secondarily to pulmonary phthisis with extreme frequency (76 per cent. of cases examined post mortem at Brompton Hospital). This has been attributed to secondary infection by the sputum, a view which is supported (1) by the onset of symptoms being generally subsequent to the formation of freely discharging vomicae, and (2) by its great frequency in laryngeal phthisis, where expectoration is difficult, and in children who do not expectorate. In children, tuberculosis primarily affecting the intestine is not uncommon; it is probably started by milk contaminated by the tubercular virus.

Symptoms.—Diarrhoea is the characteristic symptom of tuberculosis of the intestine in all its stages; before ulceration occurs the flux is easily controlled, and the early diarrhoea of phthisis is attributed to this cause. When widespread ulceration is in progress the diarrhoea is intractable; the stools are very fluid, yellowish, most offensive, and sometimes tinged with blood. There is abdominal pain, often severe, and generally localized patches of tenderness, most often found in the right iliac region; the tongue, at first red at the tip only, becomes red and glazed, and finally a brown streak forms down the centre. There is irregular but often severe pyrexia, also night sweating; exhaustion is great, and emaciation rapid. Diarrhoea is more severe and intractable when the colon is largely affected than when the ulceration is almost limited to the ileum.

Death, in the great majority of cases, is due to exhaustion, occasionally to perforative peritonitis, and still more rarely to hæmorrhage. In children, coincident tubercular peritonitis commonly has a large share in bringing about the fatal result. In less severe cases constipation may be a marked symptom, diarrhoea occurring only at irregular intervals, and then with great severity; in rare cases constipation is continuous, but, as a rule, the accumulation of solid feces irritates the ulcers and causes the attacks of diarrhoea.

Morbid Anatomy.—The tubercular new growth commences in the lymphatic tissues of the intestine, and, whether it arises in connection with a solitary gland or a Peyer's patch, extension takes place in the direction of the blood-vessels, probably in their lymphatic sheaths, and the resulting ulcer is therefore generally transverse to the long axis of the bowel. The tubercular process spreads laterally in the sub-mucous tissue; it also spreads into the muscular coat, and finally reaches the peritoneum, upon which tubercles then form; it also involves the mucous membrane, leading to destruction of limited areas. As intervening bands of mucous membrane remain at first, the tubercular plaque may have a cribriform appearance; in a later stage, which is that most commonly seen, the ulcer appears to be deep, owing to the tubercular infiltration of its edges, and the floor and sides are ragged. The floor of the ulcer is generally so much thickened by tubercular material that perforation does not occur, though the event is, taking a series of cases, by no means rare. Owing to the presence of adhesions, which form as the result of the tuberculosis of the peritoneum, the opening generally forms between two coils of intestine; even when extravasation occurs into the peritoneal cavity it is probably *guttatim*, the opening being a mere pin-point, and the acute peritonitis which ensues is commonly limited in extent, and has a conservative effect. The ulcers occasionally cicatrize, and have been known to cause chronic obstruction.

Tubercular ulceration is most common about the cæcum, but authorities differ as to whether the lower part of the ileum, the cæcum, or the colon is the earliest and the most severely affected. The mesenteric glands and lymphatics are always affected, but widespread tubercular peritonitis is seldom seen except in children or adolescents.

Treatment.—The diarrhoea is doubtless partly due to a catarrhal condition of the mucous membrane in the neighbourhood of the ulcers; the food should therefore be bland, and, to prevent overdistension of the blood, all articles which are prone to undergo decomposition, with the attendant production of flatus, should be avoided. When, from the history of the case and the presence of irregular fever with severe diarrhoea, it is probable that ulceration is in active progress, the patient should be kept warm in bed, and fed frequently with small quantities of animal broths and milk; the latter may be pre-digested, or koumiss may be given.

Poultices or turpentine stupes to the abdomen relieve pain; if there be localized tenderness, a small blister to that area will relieve it, and often check the diarrhoea. At the onset of an acute attack a dose (5j-ij) of castor oil in brandy and milk is recommended (Douglas Powell), preceded in some cases by a small dose of calomel (gr. $\frac{1}{2}$ -j). This is to be followed by bismuth subnitrate, or carbonate (gr. x-xx) combined with ipecacuanha (gr. $\frac{1}{2}$), or Dover's powder (gr. x). The use and the dose of opium must be governed by the amount of pain. Subsequently, if diarrhoea persist, vegetable astringents are of use. Tannic acid (gr. iv), logwood or fresh Indian bark may be given, but with these it will generally be necessary to combine opium. Sulphate of copper (gr. $\frac{1}{4}$ - $\frac{1}{2}$) in pill with opium (gr. $\frac{1}{2}$ -j) is a powerful astringent. In a few cases, sulphuric acid and opium is very successful. Pulv. kino co. is a convenient remedy. In the later and more chronic stages, where there is reason to suppose the large intestine to be much affected, enemata are often of great service, *e.g.*, enema opii B.P. with acetate of lead (gr. v), or tannic acid (gr. v), administered twice a

day. Some writers recommend larger enemata, preferably of linseed tea, to which tinct. opii (℥xxx-℥l) has been added; where this somewhat heroic remedy appears inappropriate, suppositories will often give satisfactory results (suppos. morphinæ B.P., suppos. plumbi co. B.P., suppos. acidi tannici B.P.). Constipation is best treated with small doses of castor oil (5j).

DAWSON WILLIAMS.

IODISM, is the condition produced by the administration of salts of iodine, and particularly the iodide of potassium. The symptoms only appear in certain individuals who show a special susceptibility to the action of the drug—*i.e.*, an idiosyncrasy. The most severe effects may follow the administration of a few grains, whilst they rarely come on in patients taking very large doses. Conjunctivitis, lachrymation, swelling of the eyelids, sneezing and nasal catarrh are early symptoms; the pharynx and gums become congested and salivation may result if mercury in any quantity be already present in the system. The patient complains of a nasty taste in the mouth, nausea, anorexia, frontal headache and tinnitus, and may have wandering neuralgic pains and palpitation. If the drug be not discontinued he gets depressed and suffers from insomnia, and eventually becomes emaciated and cachectic. Certain characteristic effects are produced on the skin which will be found fully described under the heading **MEDICINAL RASHES**. The symptoms usually soon subside if the drug be left off, but the severe bullous eruptions take some time to disappear.

ISCHÆMIA.—A synonym for local or partial anæmia; the ischæmic part when pricked does not bleed.

J

JAUNDICE (Icterus).—A yellow colour of the tissues and of certain secretions of the body resulting from the absorption of the colouring matter of the bile.

If the bile, instead of being poured into the duodenum, pass into the lymphatics of the liver, and thence into the general circulation, jaundice results.

It is usual to subdivide cases of jaun-

dice into two classes: (1) in which there is an impediment to the flow of bile into the duodenum, its retention in the biliary passages being followed by absorption and jaundice—*jaundice from obstruction*; and (2) cases in which there is no obvious obstruction—the so-called *jaundice from suppression or from suspended secretion*. It is, however, preferable to consider the subject from the point of view of the changes in the hepatic blood-

pressure and in the pressure within the bile ducts. It may be stated that the condition is in all cases due, either to (1) lowering of the blood-pressure in the liver, or to (2) a rise of pressure within the bile ducts.

The former of these conditions is observed in *icterus neonatorum*, which occurs in premature or very feeble children, where the sudden alteration in the course of the circulation produces changes in the intra-hepatic blood-pressure, and jaundice results; a similar condition may occur after the inhalation of chloroform. The production of jaundice in the latter case is probably also favoured by a rapid and excessive destruction of red blood-corpuscles which leads to a hypersecretion of bile.

The latter condition is fulfilled whenever there is *obstruction to the outflow of bile*, whether it arise from catarrhal swelling of the mucous lining of the common duct, from the presence of new growths in its walls or in the neighbourhood, which compress the duct, and either narrow or occlude its lumen, or from the presence of foreign bodies, calculi or parasites, or from cicatricial or congenital occlusion of its opening into the duodenum.

The factors which determine the flow of bile into the duodenum are (1) the pressure of the newly formed bile forcing onward the contents of the excretory ducts; (2) the interrupted compression of the liver by the diaphragm at each inspiration; and (3) the contraction of the gall bladder under nervous influences (Landois and Stirling).

All cases of jaundice must be ascribed to one or other of these conditions, or to both combined. The jaundice of *fright* or *rage* is to be attributed to lowering of the blood pressure under nervous influence. In *yellow fever* and *septicæmia* to excessive formation of bile owing to increased destruction of red blood corpuscles combined with a lower blood-pressure. In some diseases, as in *acute yellow atrophy of the liver*, we are not in a position to state precisely how these factors determine the jaundice, we only know that there is no obstruction to the outflow of bile, so that we may infer that lowering of the blood-pressure in the liver favours its entrance into the lymphatics. The early and rapid destruction of the liver cells prevents the supposition of an excessive secretion of bile, but the diffused yellow appearance of the liver shows that the bile has entered the lymphatics.

ROBERT SAUNDBY.

JAUNDICE, CATARRHAL.—Catarrh of the mucous lining of the common bile duct is most often secondary to catarrh of the duodenum, a condition which is usually due to an extension of catarrh from the stomach. The latter affection may follow errors of diet, the abuse of alcohol, catching cold, long-standing heart disease, pregnancy, enteric fever, pneumonia, Bright's disease, lithæmia, excessive tea-drinking, or malarial fever.

Primary catarrh of the bile ducts occurs in acute phosphorus poisoning, perhaps in some of the conditions above named, and from the presence of irritating foreign bodies—*e.g.*, calculi and parasites.

It occurs equally in both sexes, but more often in young persons.

Symptoms.—The symptoms necessarily vary with the ætiology of the affection and the different concomitant conditions that may be present. In ordinary simple catarrhal jaundice, however, such as occurs not infrequently in young persons, they are fairly uniform. The attack commences with considerable malaise, loss of appetite, furred tongue, bad taste in the mouth, headache and constipation. There may be also some sense of weight in the right hypochondrium. In three or four days the conjunctivæ are tinged yellow, and before this the urine contains bile pigment.

This can be recognized by the eye alone, but should be tested by diluting the urine in a glass to the colour of pale sherry and adding nitric acid, containing a certain amount of nitrous acid (as it always does after keeping a short time, when it turns a yellow colour) or some diluted liq. iodi (1 part to 10 of water), when a bright green colour makes its appearance if bile pigment be present, or some of the urine may be allowed to mix slowly with nitric acid on a white surface, such as a plate, when if bile pigments (bilirubin) be present a play of colours from green to red and violet is observed; this is known as Gmelin's test. The green is the only colour which really indicates the presence of bile pigment, as the red and violet tints are also produced by the presence of urobilin and indican in the urine.

The liver area is enlarged below the costal margin, there is often tenderness over it, and the gall-bladder may be felt just outside the edge of the rectus abdominis muscle. The stools are pale, clay-coloured and of stiff consistence; if the occlusion of the duct be complete they may be as white as curd. The pulse

is slow, probably owing to the poisonous action of the bile acids on the heart. The temperature is normal or subnormal.

Yellow vision, or "*xanthopsia*," sometimes occurs. Pruritus is often very troublesome.

The disease lasts from two to four weeks or longer. An attack of catarrhal jaundice may favour the occurrence of gall stones; and in rare cases, if long continued, may lead to general dilatation of the bile ducts or even to suppuration, and multiple small abscesses may form in the liver.

Diagnosis.—The first indication is often the appearance of bile pigment in the urine, which may be discovered even before there is any tinge of yellow in the conjunctiva or skin.

At one time some diagnostic importance was attached to the discovery of bile acids, but owing to the uncertainty of Pettenkofer's test (a purple colour with sugar and sulphuric acid) little attention has of late been paid to it. A new and very simple test has been lately suggested (M. Hay) by which results of some value may be obtained. A few grains of precipitated sulphur are sprinkled on the surface of the urine, when, if the bile acids be present, the sulphur floats, instead of sinking, as it ordinarily does. It has also been suggested (Oliver) to employ a solution of peptone, which gives a precipitate with these acids. The other diagnostic points worthy of notice are, the age of the patient, the absence of pain and the associated pathological conditions.

Prognosis.—The duration of the disease is, as has been said, from two to four or more weeks, and the prognosis is always favourable unless the condition be dependent upon some grave organic condition, such as heart disease. As a complication of pneumonia it is not a cause for alarm.

Post-mortem appearances.—In simple catarrh of the bile ducts these are not well-marked. The mucous lining is slightly swollen, and the bile in the passages may be mixed with mucus. The gall-bladder may be found distended with bile. The liver is slightly enlarged and bile stained. The stomach and duodenum present the signs of acute or sub-acute catarrh, more or less injection, and swelling of their mucous lining,

which is thickly coated with turbid mucus.

In acute phosphorus poisoning it is the smaller ducts which are the seat of the catarrh, and the gall-bladder and secretory ducts may be nearly, or quite empty, while on microscopical examination the small ducts are found to be plugged with desquamated epithelium.

In catarrh due to foreign bodies the tissue changes in the large ducts are more marked, and often accompanied by ulceration.

In very chronic cases of catarrhal obstruction the bile ducts above the obstruction become dilated and filled with bright yellow muco-purulent fluid. The liver is much swollen, stained with bile, and the walls of the gall-bladder are cedematous.

Treatment.—The general management of catarrhal jaundice involves rest in bed, milk diet, and sinapisms to the epigastrium. The free administration of mercurials at night, followed by saline purgatives in the morning, is, on the whole, the most successful method of treatment. If there be much gastric catarrh, the following remedies should be employed:—*R* Hydrarg. subchlor. gr. j, sacch. alb. gr. v; fiat pulvis, mitte duas. Sig. One to be taken at bedtime on two following nights. *R* Bismuthi carb. gr. x, sodii benzoatis gr. x, pulv. rhei gr. ij., pulv. cinnamomi co. gr. v; fiat pulvis, mitte duodecim. Sig. One to be taken thrice daily in a little milk before meals. The bismuth powders should be continued till the gastric catarrh is relieved, and the calomel may be repeated at intervals of a week. Where there is no very obvious gastric catarrh, the following mixture will suffice:—*R* Sodii benzoatis, ʒij, inf. gentiani ʒvj; misce. Sig. A tablespoonful three times a day before food. And if there be any constipation this pill may be given at bedtime: *R* Euonymini gr. j, ext. aloes gr. ij, pulv. ipecac. gr. ʒ; misce ft. pil.; mitte sex. Sig. A pill to be taken at bedtime.

A tumblerful of hot water should be sipped every morning, in which a teaspoonful of Carlsbad salts have been dissolved, or a tumblerful of Vichy water (Célestins or Haute-Rive) may be taken twice a day with lemon juice.

ROBERT SAUNDY.

K

KIDNEY, ABSCESS OF.—A collection of pus within the substance of the kidney.

Abscess of the kidney may show itself as one or more large collections of pus, usually limited to one organ, or as numerous small abscesses distributed through the substance of both glands. The latter is the variety usually associated with pyæmia.

Symptoms.—The pyæmic abscesses give rise to no definite symptoms during life which could lead to their diagnosis in the midst of the other severe symptoms of the pyæmic state. They would in most cases cause albuminuria, but this would also result from the general febrile condition. The symptoms about to be described are, therefore, those of the larger variety of abscess.

Before the advent of the suppuration the patient presents the signs of a simple acute inflammation. A feeling of heaviness and pain in the loin is complained of, tenderness is observed when pressure is applied over the kidney, while there is more or less rise of temperature together with the other usual signs of fever.

The urine is scanty and high coloured, depositing urates on standing, and it may sometimes contain blood, or albumen. The onset of suppuration is indicated by the occurrence of rigors, and sometimes by profuse perspiration. The temperature becomes higher and more variable, assuming the characteristics of the hectic state. In the loin, on the affected side, pain and tenderness are more acute. A distinct bulging may be seen, and, as the abscess increases in size, a fluctuating swelling may be felt in the usual situation of the kidney. It is to be noted that in certain cases the onset, and even the whole course, of the abscess, may be latent and unaccompanied by any definite symptoms.

The abscess may attain a considerable size, but its further course is variable. It often bursts into the surrounding parts. The most favourable course which the pus can take is to make its way into the pelvis of the kidney. Large quantities of pus are then discharged with the urine, the swelling in the loin diminishes in size, and after a time recovery takes place. A less favourable event is for rupture to take place into

the intestine; pus is discharged with the feces, but the suppuration is apt to be prolonged. Rupture into the peritoneum is fatal.

The pus may also find its way into the perinephritic tissue, constituting a perirenal abscess, and may thence burrow to distant parts, at length opening externally. The abscess may also open directly on the external surface, usually in the loins, and it has been known to extend into the thoracic cavity, discharging itself into the pleura, or through the lungs into the bronchi. All these results, however, are unfavourable; prolonged suppuration ensues, with gangrenous sloughing of the parts over which the pus flows and the patient at last dies from exhaustion.

There remain to be mentioned two issues of the abscess which are unfortunately rare. The pus may be entirely absorbed and nothing be left but a firm fibrous cicatrix. Again, the pus may become inspissated and the abscess wall shrunken, leaving a cheesy mass surrounded by a thick capsule of fibrous tissue; calcareous salts may in time be deposited in the cheesy material. Either issue is of course favourable to the patient.

Diagnosis.—In the absence of a definite tumour the diagnosis must be based upon the presence of pain and tenderness in the loin, together with fever of a hectic type, rigors, and sweatings. When a tumour has appeared, fluctuation will determine its cystic nature, while the general symptoms of suppuration will distinguish it from other like formations in the kidney. The distinction between an abscess in the kidney and one outside the organ will be found in the article on PERINEPHRITIS. (See also ABDOMINAL TUMOURS, DIAGNOSIS OF.)

Ætiology.—Suppuration in the kidney may be caused by blows on the loins, or by crushing and laceration of the renal substance, as in buffer accidents. It has been known to occur after the exhibition of irritant drugs, such as cantharides and turpentine. It may be set up by the presence of a tumour or tuberculous material, or of a calculus in the kidney substance. Suppuration is, again, the result of the lodgment of an irritating or septic embolism in the kidney, as

occurs in states of general pyæmia and in some forms of ulcerative endocarditis. Further, abscess formation is one of the manifestations of the so-called surgical kidney, the ætiology of which is discussed under that heading.

Pathology.—A large abscess may be, from the first, solitary, or may result from the amalgamation of several miliary abscesses. It shows itself as an irregular cavity, occupying more or less of the kidney substance, having ragged walls formed by pulpy and degenerated renal tissue, and is occasionally bounded by the capsule of the organ. Its contents are pus, mixed with blood and the detritus of the destroyed gland tissue.

The pyæmic abscess appears in the early stages as a wedge-shaped area of greyish colour, situated in the cortex of the kidney, with the base at the periphery of the organ. The area is from the first somewhat softened and is surrounded by a zone of hyperæmia. In a short time suppuration takes place, the area now becomes more globular than wedge-shaped, and is still surrounded by a zone of hyperæmia. Later on a more or less firm capsule of fibrous tissue limits the abscess.

Microscopically, there is seen in the early stages coagulative necrosis of the renal cells, and collections of micrococci can, by suitable staining processes, be demonstrated in the glomeruli and in the larger blood-vessels of the affected part. Sometimes streaks of purulent infiltration are present in the pyramidal portion of the kidney, running along the course of the vasa recta.

Pyæmic abscesses are the result of infective emboli which reach the kidney from some distant septic focus, and block portions of the renal vascular system. The smaller abscesses may coalesce by the breaking down of the intervening walls, and so produce one large abscess. Moreover, in ulcerative endocarditis the infective embolus may be of a sufficient size to block a considerable branch of the renal artery, and then the resulting abscess may be large from the first. Pyæmic abscesses may heal by inspissation of the pus, or by absorption of the pus and the formation of fibrous tissue by the surrounding parts. Finally, nothing may be left but a small fibrous cicatrix, which occupies the position of the destroyed kidney substance. The suppuration caused by tumours and calculi is localized to the vicinity of the irritating body.

Treatment.—The patient should be

kept at rest in bed, and on light fluid diet. The bowels should be maintained freely open by enemata or a mild saline purge. In the early stages, wet cupping, or the application of leeches to the loins, may be employed with advantage, and will occasionally avert the more serious symptoms. Poultices or hot fomentations to the loins will help to relieve the pain and tension, but opiates may be necessary to obtain rest and ease. As drugs, febrifuges are indicated, the citrate and acetate of potash in half-drachm doses, and the liquor ammonii acetatis being the most useful.

When distinct signs of suppuration have appeared, quinine should be administered freely. If the abscess has ruptured, the strength should be maintained by a full diet, stimulants, and the various preparations of bark, in order to ward off as much as possible the effects of prolonged suppuration. The untoward results of leaving the abscess to work its own discharge must be remembered. Therefore, whenever it is certain that pus has formed in the kidney, it should be let out by an incision in the loin, and the abscess cavity drained. It is quite justifiable also to make an exploratory incision when suppuration is suspected but not absolutely determined.

ROBERT MAGUIRE.

KIDNEY, CYSTS OF.—Cysts occur in or near the kidney under a variety of conditions.

1. Cysts are found with great frequency in connection with granular kidney. They are due to obstruction to the renal passages by the fibrosis of the organ, and their anatomy is described elsewhere.

2. In otherwise healthy kidneys it is not uncommon to find cysts of variable size, but rarely larger than a walnut, filled with usually diffuent, sometimes gelatinous, material. They rarely give rise to symptoms, but may occasionally attain such a size as to constitute an important abdominal tumour. They are probably due to obstruction of a renal tube, the cause of which is, however, unknown.

3. **Congenital Cystic Degeneration.**—As a congenital condition, both kidneys are occasionally found riddled with cysts, which seem to have taken the place of almost the whole of the secreting structure. The kidneys are greatly enlarged, and may constitute an obstacle to delivery. The cysts are lined by tessellated epithelium, and are surrounded

by fibrous tissue and by a certain amount of renal tissue.

The fluid contained in the cysts consists of urine, together with albumen, blood, fat granules, and cholesterin. It may be quite colourless and transparent, but more often is cloudy, and coloured brownish-red or yellow. The renal artery in connection with such a cystic kidney has been shown by Rindfleisch to be much narrowed.

Often other malformations of the genito-urinary organs and other parts are found; and if, as occasionally happens, cystic kidney be present on one side only, the other malformations are also limited to that side.

Pathology.—The cysts are due to obstruction and distension of the urinary passages. The cause of such obstruction has been variously explained. Virchow asserted that the occlusion of the tubes was produced by inflammation of the papillary ducts from the impaction of uric acid or urates in the straight tubes. Köster, on the other hand, shows that the tubuli uriniferi may not establish their normal communication with the renal pelvis, which is formed from the Wolffian duct, and so may remain impervious. Thorn believes that inflammation of the ducts may spread from the pelvis and calices of the kidney, and so cause occlusion; while Chotinsky has found that proliferation and accumulation of epithelial cells may block the tubes. Bland Sutton has recently suggested that it is not the uriniferous tubes which are dilated, but remains of the Wolffian duct.

A considerable degree of this affection is incompatible with life. As to how far a minor degree may persist to adult age is not known; but such a persistence may possibly be a cause of the form next to be described.

4. Cystic Degeneration of Adults.—In adults both kidneys are sometimes found converted into immense masses of cysts, occasionally, strange to say, without any definite symptoms having been presented during life. Both kidneys are always affected, though not necessarily to the same degree. The cysts vary in size, from a pin's head to an orange. Their walls are lined by flat epithelium, and the fluid within them is either a gelatinous substance or a clear, yellowish liquid. The fluid contains albumen, cholesterin, phosphates, uric acid, creatine, and occasionally other urinary ingredients. The cysts are imbedded in a mass of fibrous tissue, in which but little of

the true secreting parts is to be found. The lower urinary passages are generally healthy.

The cysts have been thought to be dilated Malpighian capsules, but are probably renal tubes, which have become distended in consequence of obstruction to their lumen. The obstruction has probably a similar origin to that occurring in the congenital form.

It would appear that in a large number of cases the interstitial fibrosis is the primary lesion, as in the cysts which accompany granular kidney. Possibly in some cases blood clot may cause the obstruction of the urinary tubes.

Symptoms.—The symptoms may be entirely absent; they are rarely very distinctive, and are always chronic in their progression, and are practically those of chronic Bright's disease. The urine is commonly of low specific gravity and often contains albumen and blood. The heart may be hypertrophied and symptoms of chronic uræmia, such as vomiting and nausea, headache and delirium, may present themselves. In the final stage if death occur from the kidney affection there are manifestations of uræmic coma and convulsions, which not unusually are sudden in their onset. In spite of the increased size of the kidneys it is not always possible to feel them during life through the abdominal wall. They lie deep down in the lumbar regions, completely filling up the hollows on each side of the vertebral column.

Treatment.—The treatment must be that of chronic Bright's disease, with which, both pathologically and clinically, the disease has great similarity.

5. It is sometimes observed after death that the kidneys, together with the liver and sometimes the spleen, are the seat of numerous cysts of about the size of a pea. The organs are not more than slightly enlarged. The nature of the cysts is not yet precisely known; in some instances they appear to be dropsical distensions of the epithelial cells, in others to be mere spaces in the tissue, filled with serous fluid. They must be distinguished from a similar change which is sometimes the result of putrefaction. No symptoms have as yet been connected with this condition.

6. Para-renal Cysts are occasionally seen which take their origin outside the kidney, although they may eventually communicate with its interior. Their origin is unknown. They are but rarely so large as to be of clinical importance.

7. Hydatid Cysts are described under the head of KIDNEY, PARASITES OF.

ROBERT MAGUIRE.

KIDNEY, MISPLACED.—The kidney is liable to be displaced from its normal position by the pressure of tumours or of inflammatory exudations. Such a displacement has in itself no clinical importance.

As a congenital condition the kidney may occupy a position lower or higher than is normal, and sometimes both kidneys may be situated on the same side of the abdomen.

Of these misplacements the most common, and also the only one which has any clinical interest, is the misplacement downwards. In the foetus the kidneys lie near the bifurcation of the aorta, and occasionally one of them remains in this position even in adult life, most commonly resting on the sacro-iliac synchondrosis. The renal artery has a similar low origin, arising from the aorta near its bifurcation, or from the common iliac artery or from the middle sacral artery. The vein also enters the inferior vena cava at a corresponding level.

The vessels and ureter not infrequently show abnormalities of number. The kidney itself lies somewhat obliquely, and has a more or less abnormal configuration. The supra-renal body of that side occupies its normal site, but congenital malpositions of the intestine or peritoneum may be present. The condition is the more common in men, and most frequently it is the left kidney which is misplaced.

The clinical importance of this condition lies in the fact that, from its prominent situation, the kidney may be mistaken for an abdominal tumour. It is on record also that such a kidney lying in the pelvis caused an obstacle to parturition. The size and elastic feel of the mass, possibly its renal shape, the sickening feeling produced by pressure, the apparent emptiness of the normal site of the kidney, the presence of the supposed tumour on the left side, and the male sex of the patient, will serve to establish the diagnosis.

Another congenital deformity, the **Horseshoe Kidney**, may occasionally give rise to pathological changes. In this condition the two kidneys are joined together, generally at the lower, but sometimes at the upper, end by a connecting band, which is composed either of true renal substance or of firm fibrous tissue. The kidneys are lower

in the abdomen and nearer the vertebral column than is usual, and there are always found abnormalities in the distribution of their blood-vessels. The connecting band may be felt during life and mistaken for a tumour. Any disease, such as pyelitis attacking such kidneys, would be accompanied by an unusual localization of the physical signs. One case is on record in which a congested horseshoe kidney pressed on the inferior vena cava and caused thrombosis and death.

ROBERT MAGUIRE.

KIDNEY, MOVABLE (Floating Kidney).—A condition in which the kidney is no longer fixed in its normal position, but is capable of displacement over a certain area of the abdomen, under the influence of its own weight or of the respiratory or other movements.

Symptoms and Signs.—When the abdomen is examined, unless the kidney be for the moment occupying its normal position, it can be felt as a firm elastic body of the peculiar renal shape, which can be moved more or less freely, and slips from under the hand with an ease which is characteristic. The movement of the kidney may be very limited, or, on the other hand, may extend over an area of several square inches. The normal position of the kidney feels empty, and is more resonant on percussion than is usual. In most cases the kidney can readily be replaced, but in others it seems to have contracted adhesions which retain it more or less firmly in its unwonted site. The normal bed of the kidney, too, is liable to become filled up with fat, which hinders the replacement of the organ.

After replacement, a deep inspiration or certain movements frequently known to the patient, such as the raising of the lumbar region on turning to the opposite side, will again displace the kidney. On pressure, a sickening sensation is experienced. During menstruation the organ becomes larger and more tender than at other times.

There may be no symptoms whatever to attract attention to the condition. Usually, however, some pain is complained of in the loin of the affected side. The pain is aching and dragging in character, sometimes severe and shooting, and it may be accompanied by neuralgic pains in other parts of the body. The pain is worse when the patient stands or moves, and is relieved or disappears when the recumbent position is assumed.

Dyspepsia, epigastric pulsation and irregularity of the bowels, at one time diarrhoea at another constipation, are common symptoms. Frequency of micturition has been sometimes noted. The aching pain and consciousness of the abnormality after a time induce a condition of hypochondriasis.

While the symptoms usually complained of are vague, there occur at times paroxysms resembling those of renal colic, during which the patient suffers great pain, radiating from the kidney downwards in the direction of the ureter, and accompanied by vomiting and faintness. The displaced kidney during this attack is swollen, tender, and less freely movable than it was before. Such paroxysms are induced by excessive exercise or an indigestible meal, and are specially liable to occur at the menstrual periods. The urine during one of these attacks may contain blood or pus, whereas its usual condition is normal.

Edema of the lower limbs, from pressure of the displaced organ on the inferior vena cava, has been observed. Jaundice also may occur from pressure on the bile duct. No alteration in the composition of the urine can be observed, as a rule; but the pyelitis, which may appear as a transient phenomenon during the paroxysmal attacks, occasionally becomes permanent, and pus will then be found in the urine.

Pathology.—It is sometimes found that the peritoneum, which ordinarily passes only in front of the kidney, actually envelops it, so as to produce a mesonephron. This is a congenital condition, and it allows of a movement of the kidney, which is only restrained by the attachment of its vessels. But any process which loosens the kidney from its bed, or diminishes the support it receives from the other abdominal contents, will tend to produce undue mobility. Thus, blows on the kidney region, muscular strains, absorption of the peri-renal fat, a swelling of the kidney from any cause, with subsequent reduction in size, and the lax condition of the abdominal walls which is induced by repeated pregnancies, are the most usual precedents. Tight-lacing, too, has been recognized as a cause, and it has been suggested that undue heaviness of the kidney from congestion during the menstrual periods may cause the organ to leave its place and stretch its supports.

The condition is more frequent in females, and in the greater number of cases is situated on the right side. It

has been suggested that the term "floating kidney" should be reserved for those cases where a distinct mesonephron is present, and all other cases designated by the term "movable kidney."

The nature of the paroxysmal attacks described is not yet clear. They may be due to pressure of the kidney upon the nerves which surround it, or to a twist of its pedicle, which would cause strangulation of its vessels or of the ureter.

The movable kidney is liable to be attacked by disease, as is the normal organ. Inflammation around it may bind it in a new position. It has been found to show the condition of granular kidney. Pyelitis is not infrequent, and extension of suppuration to the body of the organ has caused death. Hydronephrosis has been met with in a certain number of instances, and is probably due to a bend and obstruction of the ureter when the kidney is displaced downwards.

Diagnosis.—The diagnosis of movable kidney is easy. Its peculiar mobility, its shape and elasticity, the ease with which it can be pressed into and out of the lumbar space, and the emptiness and comparative resonance of the lumbar space when the tumour is felt in the abdomen, are signs which in most cases are easily detected, and at once suggest the nature of the condition. (See ABDOMINAL TUMOURS, DIAGNOSIS OF.)

Treatment.—If, as frequently happens, no very distressing symptoms be associated with mobility of the kidney, no treatment whatever is required. But the hypochondriasis and neuralgic pains sometimes render life a burden, and hinder the patient from undertaking any active duties. If this be so, an attempt should be made to retain the kidney in its place. This, in a few instances, may be effected by a simple abdominal bandage to give support to the walls, and a pad over the front of the kidney region. The bandage and pad should be applied while the patient is in the recumbent position. An india-rubber belt with an air pad over the kidney, as recommended by Dr. Newman, is even more effective. For more intractable cases Dr. Dickinson has found a spring truss, to press on the kidney region, very serviceable, but its pressure cannot always be borne.

If all these appliances fail, and the symptoms are still distressing, the kidney may be fixed in its normal position by the operation of nephrorraphy, in which

the kidney is stitched to the posterior abdominal wall through a lumbar incision, and is afterwards retained in its position by inflammatory adhesions. The results of this operation, as at present observed, are, however, not very encouraging, as in several cases the organ has again become movable. Excision of the kidney has been recommended as a last resource, but is too dangerous, and should not be advised.

The bowels should be maintained in a state of regular activity. If there be anæmia and lassitude, iron and other tonics are indicated. Violent exercise is to be forbidden and also such movements as have been found to occasion the displacement should be avoided.

During the paroxysmal attacks absolute rest in bed must be maintained, poultices and other anodyne applications should be used to alleviate the pain in the displaced kidney, and opiates administered by the mouth or subcutaneously.

ROBERT MAGUIRE.

KIDNEY, PARASITES OF.—

I. **HYDATIDS.**—The cystic condition of the tænia echinococcus, is the most common parasite of the kidney in England. It is nevertheless rarer in this organ than in the liver and lungs.

The left kidney is the more frequently the seat of the parasite, possibly owing to the fact that as the liver is so frequently the host of the hydatids a larger proportion of embryos travelling from the intestine are free to attack the kidney on the left side than on the right.

The cyst may be small or may attain the size of a man's head. It is lodged in the substance of the kidney, or may in some instances lie between the capsule and the organ itself. In either case, as its size increases, atrophy of the kidney substance is caused from pressure. The structure of the hydatid cyst is described in the article upon **HYDATID DISEASE**. Men are more liable to hydatids of the kidney than women. The mean age at which they make their appearance is thirty-four years.

Symptoms.—A small cyst may exist without any symptoms whatever being observed.

As the cyst increases in size it forms a tumour in the lumbar region, tense, elastic, sometimes fluctuating and presenting all the evidences of a tumour of the kidney already described. It is to be noted that the colon does not always lie over the front of the hydatid cyst, but may be on either the inner or

the outer side. The viscera of the neighbourhood may be displaced by the increasing size of the cyst.

The cyst sometimes, when percussed, communicates to the hand or stethoscope laid upon it the peculiar vibration termed the "hydatid fremitus," which is, however, probably nothing more than the vibration of a tense cyst wall.

Local pain and tenderness, which are usually absent, are nevertheless sometimes produced by inflammation of the surrounding tissues. Such inflammation causes transient pyrexial attacks, and occasionally passes on to suppuration.

The symptoms above described are merely those of any other cystic formation in the kidney. The hydatid cyst, however, shows a great tendency to make its way towards the pelvis of the kidney and to burst into the urinary passages. This it effects the more readily if it be originally situated in the pyramidal portion of the organ; after a longer time, if localized in the cortex or outside the kidney. By this peculiarity, symptoms are occasioned which are characteristic of the disease. The passage of the daughter cysts contained in the parent sac down the ureter, gives rise to the phenomena of renal colic, similar to those accompanying the descent of a calculus—pain in the course of the ureter, in the groin and the inside of the thigh, retraction of the testicle, vomiting and retching, with sometimes rigors.

These symptoms subside when the small cyst has reached the bladder, but when the cyst afterwards attempts the passage of the urethra it causes blocking of the canal, with frequent efforts at micturition, pain, and retention of urine, until at last it is expelled, often with some force. The urine passed at the same time may contain blood or pus. Not unfrequently the cyst ruptures in its transit, and there is then discharged from the bladder shreds of hydatid tissue, hooklets and fat globules. The symptoms recur at irregular intervals as more cysts proceed down from the kidney.

The rupture of the parent cyst is sometimes determined by an injury to the side or a sudden exertion. The discharge of vesicles often causes a notable diminution in size of the tumour in the loin, while, again, renal distension may ensue upon obstruction of the ureter by a passing cyst.

Results.—In the majority of cases recovery ensues, the contents of the parent cyst being discharged into the urinary passages. The cyst has also

been known to rupture into the lung and into the intestines, but never into the peritoneum. The sac may itself suppurate or may cause suppuration in the surrounding parts; further, the hydatids may die and the sac shrivel up into a cheesy or even cretaceous mass containing numerous hooklets.

Diagnosis.—When the cyst is intact it can hardly be diagnosed with certainty. Its signs are those of any other cyst of the kidney, except that the colon is more irregularly placed than is the case with other cysts. It most nearly resembles a hydronephrosis, but the history of any possible obstruction to the ureter, which would cause a hydronephrosis, is of course wanting. In obscure cases puncture of the cyst may be practised, not only for purposes of treatment, as is mentioned below, but also to establish the diagnosis. If the fluid withdrawn contain hooklets, or be free from albumen and rich in chloride of sodium, the nature of the cyst is obvious.

When a tumour in the loin is accompanied by the presence of hydatid elements in the urine, no difficulty will be experienced. The urinary appearances may, however, be present without a tumour in the loin, and then the kidney can only be diagnosed as the origin of the hydatids after the pelvis and inguinal regions have been carefully explored with a negative result, or when pain in the loins or nephric colic has been experienced.

Prognosis.—The prognosis is usually favourable, especially if the cyst have ruptured into the urinary passages. Rupture into other parts may be followed by suppuration or gangrene, leading often, but not necessarily, to a fatal result.

Treatment.—It has been suggested on various occasions that hydatids of the kidney might be destroyed by the internal use of drugs, such as turpentine, iodide of potassium, nitre, &c.; but such medicines, in the cases where good effects have seemed to follow their use, have probably acted only as diuretics and not as vermifuges.

When the cyst has ruptured, the pain accompanying the passage of the vesicles along the ureter should be allayed by the various remedies for renal colic—anodynes, warmth, and diluents. The vesicle has been assisted in its course by a kneading of the ureter in the direction of its length. The catheter may be required to relieve obstruction to the urethra.

Should the cyst remain unruptured its cure may be attempted by tapping, either with the aspirator or a syphon-tube. The removal of only a small amount of fluid often suffices to cause the death of the parasite and the ultimate obsolescence of the sac. Should these means fail, the sac should be exposed, an incision made, and the edges stitched to the wall of the abdomen, the operation being, if possible, performed in the loin.

II. *BILHARZIA HÆMATOBIA.*—This worm, known also by the names of *Distoma Bilharzii* and *Distoma Hæmatobium*, is a common parasite of the urinary organs in hot climates.

It is probable that fresh-water molluscs and fish are the hosts of the parasite during its transition stages from the embryo to the adult worm.

To the description of the parasite already given under the above heading (*q.v.*) it need only be added that the worm gains access to the body of man by means of drinking water, or fresh vegetables which may contain the animal itself, its embryo or the ova. Possibly, too, it may attach itself to the skin of a person bathing in infected water, and so reach a superficial blood-vessel.

The special habitat of the parasite in the body of man is the small veins, particularly those of the portal and urinary systems. In the bladder, ureter and kidneys it gives rise to extensive mischief. On the mucous surface of the bladder it produces ecchymotic patches slightly raised above the general surface, sometimes covered by a greyish membrane or by tough mucus. Nodular enlargements, over which the mucous membrane is intact, are also found. Covering the patches a mass of debris is frequently seen, consisting of the ova of the parasite, mingled with a deposit of uric acid and other urinary salts. Such an accumulation of eggs and urinary concretion is occasionally the cause of a distinct vesical calculus. In the kidney the presence of the parasite sets up severe pyelitis, and the calibre of the ureter may be narrowed. In certain cases by a combination of these two conditions the kidney has been converted into a mere sac of pus.

Symptoms.—The special symptoms produced are those of severe cystitis or pyelitis, and a recurrent hæmaturia (endemic hæmaturia). Such symptoms being observed, the diagnosis of their cause may be made when the eggs of the worm are found as a urinary deposit.

The free embryos, and the emptied egg-cases from which the embryos have escaped, also make their appearance in the urine.

Treatment.—Dr. Harley recommends that a morning draught be given containing oil of turpentine and male fern (of each mxxv), with mij of chloroform and ʒij of tragacanth mixture. Bicarbonate of potash in freely diluted solution is of use to relieve renal irritation and to facilitate the breaking up of concretions. Injections into the bladder of a solution of iodide of potassium (20 to 30 grains in 5 ounces of tepid water) used every second or third day were found beneficial when the parasite was specially localized in the walls of the bladder. As prophylaxis it is recommended that drinking-water should be filtered, and all salads or uncooked molluscs and fish avoided (*see also* BILHARZIA).

III. *FILARIA SANGUINIS HOMINIS*.—The effects of this worm are described in the articles upon *FILARIA* and *CHYLURIA*.

IV. *STRONGYLUS GIGAS*.—This worm is of extreme rarity in man, and is only found in the kidney.

It is a nematoid worm, resembling closely the *ascaris lumbricoides*. It is, however, much longer, the male being nearly a foot in length, and the female nearly a yard. It is also redder in colour than the round worm, and has six papillæ round the mouth. The symptoms produced by it are unknown.

V. *PENTASTOMA DENTICULATUM*.—This small parasite has only been found once in the urinary organs of man. It is encysted and club-shaped, and gives rise to no symptoms.

VI. *COCCIDIUM OVIFORME*.—A few instances have been described in which this parasite presented itself in the form of psorospermial sacs in the kidney and in the mucous membrane of the pelvis and ureter. It is not known if its presence causes any symptoms (*see* PSOROSPERMIE).

VII. *ERRATIC WORMS*.—Various parasites from the intestine, such as the thread-, round-, and tape-worms, occasionally obtain access to the urinary passages, and are discharged in the urine.

ROBERT MAGUIRE.

KIDNEY, TUBERCLE OF.—Tubercle may affect the kidney in three different ways, as—1. Miliary Tuberculosis; 2. Caseating Tubercle; and 3. Tubercular Pyelitis, leading to Pyelonephritis.

Symptoms.—Miliary tuberculosis, as a rule, gives rise to no symptoms by which it can be diagnosed.

The symptoms of caseating tubercle and of tuberculous pyelitis are, for practical purposes, identical. In the early stage there is pain in the lumbar region of one or both sides, often shooting downwards in the course of the ureters. The urine contains pus, and occasionally a little blood. In exceptional cases, hæmaturia may be a prominent symptom at the beginning of the disorder. Frequency of micturition is an early and characteristic symptom; and when this is combined, as is sometimes the case, with pain in the region of the bladder, a suspicion of the presence of vesical calculus may easily arise. Yet both these symptoms may be entirely independent of any affection of the bladder itself.

When the disease is fully developed the urine is feebly acid, and contains a large quantity of pus, with often a little blood. On standing for a short time the urine yields a deposit, consisting of pus corpuscles, blood corpuscles, a quantity of granular débris. When the pelvis of the kidney or the ureter is affected and the disease therein has not proceeded very far, a number of epithelial cells of irregular shape, which have desquamated from the mucous membrane of those parts, may sometimes be found.

When appropriately stained, the deposit may be shown to contain tubercle bacilli. The writer, however, would point out that it is by no means so easy to demonstrate the bacilli in urine as in the sputum from a phthisical lung. Possibly this is due to the extreme chronicity of the tuberculous process in the kidneys, and the consequent scanty discharge of bacilli into the urine.

Hyaline and, occasionally, granular casts are deposited. Albumen, too, is present in the urine, but not usually in much greater amount than the co-existent pus will account for.

The quantity of urine excreted may be normal or somewhat diminished, but it has been known to be large, and the urine is then of diminished specific gravity. Occasionally, too, while the urine, at ordinary times, presents the abnormal signs enumerated above, it happens that, for short periods, it becomes limpid, copious, non-albuminous, and gives no deposit after standing. Doubtless, these variations are indicative of a unilateral affection, the ureter of the diseased side becoming occasion-

ally blocked, and thus permitting the passage of an unmixed secretion from the opposite normal, or possibly hypertrophied organ.

Even when tubercle is limited to the kidney itself, the enlarged organ may be felt in the lumbar region on deep pressure. Tenderness in the same region can nearly always be elicited. But when tubercle has attacked the renal pelvis and pyonephrosis is established, the customary sign of this condition—painful, tender and obscurely fluctuating tumour in the flank—is manifest. The tumour may vary in size coincidentally with changes in the character of the urine.

Meanwhile, constitutional symptoms of tuberculosis, albeit but ill-marked in the early stage, become more and more evident. Hectic fever with chills, rigors, frequent and feeble pulse, and great emaciation are added to the symptoms already described. There may have been, at the first appearance of kidney trouble, evidence of tubercular disease in the lungs of old standing, but even when the kidney disease has apparently been primary in origin the lungs and the alimentary canal in the advanced stages of the affection often show signs of secondary infection.

Destruction of kidney substance, or obstruction to both ureters, may cause death from uræmia. The end may also be induced by exhaustion from prolonged suppuration. Further, a complication, such as an affection of the lungs or intestines, spread of the kidney affection to neighbouring parts, or rupture of an abscess into the peritoneum, may destroy life.

Diagnosis.—The symptoms of chronic tuberculosis are mainly those of pyelitis, and the question of diagnosis is as to the cause of the pyelitis. The presence in the urine of granular debris, caseous masses, connective tissue or elastic fibres is a most characteristic feature of the tuberculous affection.

The discovery of the tubercle bacillus in the urine of course places the nature of the affection beyond doubt. Nevertheless, the detection of the bacillus in the urine is not an easy matter, and it may be absent in undoubtedly tubercular cases, so that too much stress must not be laid upon this method of diagnosis. The bladder symptoms will sometimes create a suspicion of vesical calculus, especially in the early stages, and the surgeon may have to be called in to assist in the diagnosis by the aid of the sound. Affection of the lower urinary tract or of

the genital organs, will, if present, differentiate tubercular from calculous pyelitis. Also, in both calculous and cancerous pyelitis there is usually more hæmaturia than is present in the tubercular form. The hectic fever and wasting of tuberculosis and especially the signs of tuberculosis elsewhere in the body, afford most valuable aid in making the diagnosis.

Prognosis.—Miliary tuberculosis of the kidney is always part of a general fatal process. The prognosis of chronic tuberculosis of the kidney is exceedingly grave. Nevertheless evidence of a healing process has been occasionally found in the kidney after death. If one kidney only be affected and the other organs of the body be healthy, it would seem possible that the affected organ might become shut off from the urinary passages and the tubercle become obsolete. This condition is indeed sometimes found after death from other diseases, although unsuspected during life. When both kidneys are affected, or other organs are seriously diseased, only a fatal prognosis can be given. The duration of the disease is from a few months to three years, rarely longer.

Pathology.—Miliary tuberculosis of the kidney is always part of a general outbreak of acute tuberculosis, secondary in many cases to a caseous focus elsewhere in the body. Both organs are the seat of nodules, not usually very numerous, of varying size, the largest being about equal to that of a pin's head. The smallest nodules are grey in colour and almost transparent, the larger ones are more opaque, and may present a small yellow spot of caseation in the centre. Round each a zone of congestion may usually be seen.

The nodules are most numerous in the cortical portion near the surface of the organ, in the medullary portion but few are to be found. Their position is determined by the distribution of the arterioles with which they have an intimate relationship.

On *microscopic examination*, the nodules are seen to consist of the ordinary elements of tubercle, giant cells, epithelioid cells, and some smaller round cells. The larger nodules are often composed of amalgamated individual tubercles. The interstitial tissue is the favourite seat of the tubercles, but they may also be found in the interior of the urinary tubes and also in the glomeruli.

Tubercle bacilli are found in large numbers in the nodules and have been

described as filling the small blood-vessels.

Secondary changes are also seen. The epithelium of the convoluted tubes throughout the kidney may show degenerative changes and even necrosis. The centre of the nodules is often necrosed and caseous, and the glomeruli and surrounding tissue sometimes share the same fate. Necrosis is occasionally more massive. Small anæmic infarcts of thrombotic or possibly embolic origin, are not infrequently observed. Miliary tubercles of the kidney are more common in children than in adults.

Caseating tubercle may be primary in the kidney, and although it is frequently accompanied by tuberculous lesions in other parts of the body, these are, as a rule, less advanced in development than the kidney affection. In its earlier stages the lesion has the form of grey or yellow nodules in the substance of one or more of the medullary pyramids. The nodules enlarge, coalesce, caseate, soften in the centre, and spreading at the periphery, make their way into the pelvis of the kidney, and also towards the cortex.

In this way irregular cavities are formed, filled with caseous, putty-like material and communicating freely with the urinary passages. In addition to the extension from the periphery of a nodule, fresh nodules form in the cortex by infection, through the medium of the lymphatics and blood-vessels. Moreover, there is reason to believe that the tuberculous process may be continued in the epithelium of the urinary tubules and thus also proceed towards the cortex. By extension of the tubercle in these ways the whole of the kidney substance may successively be attacked and destroyed.

Associated with this lesion, there are often found tuberculous lesions of the ureters and bladder, and, in the male, of the testes and vesiculæ seminales. These may be secondary to the kidney tubercle, infection being carried down by the discharge of tuberculous material into the urine. But in some cases the tuberculosis of the genital organs or of the bladder appears to be primary, and to be communicated to the kidney by means of the lymphatics.

Tuberculous pyelitis shows itself by the presence of tuberculous matter in the sub-mucous layer of the pelvis of the kidney. The mucous membrane becomes inflamed, the tuberculous mass caseates, softens and by ulceration makes its way through the mucous membrane to the

general cavity of the pelvis. The walls of the pelvis are then converted into ulcerated, pus-discharging surfaces.

The ureter also is similarly affected, and is changed into a rigid tube, the lumen of which may be much narrowed or even obliterated, either by tubercle in its walls, or by thick caseous material conveyed into it from above.

The blocking of the ureter leads to distension of the pelvis of the kidney by the accumulation of inflammatory and degenerated products, and to the formation of a pyonephrosis. While the tuberculous pyelitis may be the continuation of a caseating tubercle of the kidney, it may itself lead to destruction of the kidney-substance, partly by invasion of tubercle, partly by pressure of retained pus, and finally nothing may be left of the organ but a sac with thickened fibrous walls, filled with a yellow creamy or putty-like material containing fatty masses, cholesterol, tubercular débris and sometimes calcareous matter.

As will be seen from the above description, caseating tubercle of the kidney and tuberculous pyelitis, by the progress of each affection, lead in the end to the same condition which is sometimes termed the "Scrofulous" kidney. The microscope reveals the tuberculous nature of the change, and that not only the cellular elements of tubercle, but also the tubercle bacillus, are present in the diseased parts. In certain cases the process oversteps the bounds of the kidney and spreads to the neighbouring organs and tissues; the softened kidney may even burst into the peritoneum.

Ætiology.—This form of tuberculosis is a disease of adult life. It may be limited to one side, but frequently affects both kidneys, albeit more advanced in one than the other. It is more common in males than females.

Treatment.—The treatment can in nearly all cases be palliative only, and is the same as that of chronic pyelitis from other causes. (*See PYELITIS.*)

Opiates, the warm bath and anodyne applications may be prescribed for the relief of pain. Iron, arsenic and cod-liver oil serve to maintain the general strength.

Nephrotomy may be performed when there is considerable pus-accumulation in or around the kidney, and the abscess cavity may be drained and treated on ordinary surgical principles. Removal of a scrofulous kidney has been resorted to with the object of relieving the patient from a suppurating focus which would be

liable to cause exhaustion and albuminoid disease, or with a view to entirely eradicate the tuberculous disease, when it is confined to one kidney. The applicability of nephrectomy to this class of case is, however, as yet open to question. Before such an operation is performed it is desirable one should know that the opposite kidney is sound. From ordinary physical examination this cannot be certainly ascertained, but Dr. Newman has found it possible to determine the point by catheterization of the ureters and separate examination of the urine from each kidney. But if both kidneys be affected we have no means of estimating surely how much healthy and physiologically available renal structure will remain after removal of one greatly diseased organ. Valuable aid may, however, sometimes be obtained by determining the quantity of urea excreted daily. ROBERT MAGUIRE.

KIDNEY, TUMOURS OF.—The tumours of the kidney are malignant and benign.

MALIGNANT TUMOURS occur in the kidney as both primary and secondary formations. The secondary tumours are not usually large, are generally found in both kidneys, and are seldom of any clinical importance. Their situation in the kidney is irregular, and depends upon the spot in which the infecting matter finds rest.

Primary malignant tumours of the kidney may attain a great size. They attack, as a rule, one kidney only, neither side being especially preferred. The extremes of life, rather than the middle periods, seem to be most prone to their development. The tumour most commonly begins in the cortex of the kidney, but it may originally be situated beneath the capsule, or in the sub-mucous tissue of the pelvis of the organ. Its consistence is nearly always that of an encephaloid growth, and even though large it retains, to a great extent, the rough outline of the kidney. The tumour spreads according to the ordinary laws of such growths, along the course of the blood-vessels, or lymphatics, or by contiguity to the neighbouring parts. It very rarely infects the lower urinary passages.

Sarcoma.—This is the most common malignant tumour of the kidney. It may consist of small round cells, occasionally arranged in alveoli (alveolar sarcoma) or, less commonly, the cells are spindle-shaped. The sarcoma is often very vascular, and contains large hæmorrhages.

It soon makes its way into the pelvis of the kidney.

A remarkable variety of sarcoma found here in rare instances is that containing striped muscular fibres (rhabdo-myosarcoma). This, it is believed, develops from remnants of either the protovertebræ or the Wolffian body. Other varieties of sarcoma which are met with in the kidney are the adeno- and the myxosarcoma.

Melanotic tumours are sometimes found in the kidney secondary to similar growths elsewhere, and are usually of sarcomatous nature.

Carcinoma is much less common. It starts occasionally in the Malpighian corpuscles, or these may be imbedded in the cancerous stroma. Again, the cancerous tissue may be a mere intrusion into the kidney substance, causing atrophy of the proper renal elements, or it may apparently be a conversion of the kidney tissue into malignant growth. Carcinoma rarely communicates with the pelvis. It may be present in the forms of encephaloid, scirrhus or colloid carcinoma or of epithelioma.

Adenoma of the kidney is never large enough to become of clinical importance. It is a tumour nearly allied to carcinoma, and consists of glandular structure, varying in its characters according to the portion of the kidney in which it may arise. Thus it may exhibit the features of either the convoluted or straight tubes. Lymphadenoma also may attack the kidney when it is present in other parts.

BENIGN TUMOURS but rarely attain a sufficient size to be of clinical importance. It will be unnecessary to do more than enumerate them. There are here found fibroma, angioma, lipoma, myxoma, enchondroma, osteoma, and villous papillomata, which, however, are often sarcomatous. Further, in leucocythæmia small growths are sometimes found in the kidneys, consisting of accumulations of leucocytes. Lastly, Grawitz and others have described curious small tumours in the kidneys, which have the structure of the adrenal bodies, and are probably instances of aberrant growth.

Symptoms and Signs.—An enlargement of the kidney, whatever its cause or nature, has the following characters. It is situated in the lumbar region of the abdomen, its centre opposite to, or slightly above, the level of the umbilicus. It projects towards the front of the body, rarely towards the back. It is usually immovable during respiration. Nevertheless, not infrequently, a great enlarge-

ment will move downwards to an appreciable extent in inspiration, retiring in expiration; moreover, the examiner's hands, placed one in front and one behind the enlargement, can often move the growth over a considerable area. The mass is rounded at all parts; sometimes, according to its nature, presenting rounded knobs on its surface. The hand can detect an interval between the kidney enlargement and the liver or spleen above, the pelvis below. On percussion the tumour itself is dull, but, since it lies behind the large intestine, the dulness is crossed from above downwards by a more or less vertical band of resonance produced by the gas-distended colon, and may sometimes be entirely covered by intestinal resonance. (*See ABDOMINAL TUMOURS, DIAGNOSIS OF.*)

There may or may not be changes in the urine, such as the presence of albumen, blood or pus, for a tumour of the kidney may not open into the urinary passages; and, further, the urinary passages of the diseased side may be blocked, and healthy urine from the sound kidney alone reach the bladder.

The enlargement presses on surrounding parts, and thus may cause oedema of the legs, varicocele and superficial venous distension from pressure on the veins, constipation or diarrhœa, from pressure upon, and irritation of, the bowel, and vomiting and nausea, from disturbance of the stomach. Such are the usual symptoms and signs of renal enlargement, but, as might be expected, they are subject to occasional variations.

The tumour may be so large as to entirely fill the abdomen. The intestines may be pushed quite to one side. The growth may affect one portion only of the kidney, and thus appear in an unusual situation. Also, enlargement may occur of a kidney abnormally placed.

The special character of hydro- and pyo-nephrosis, and other cystic tumours of the kidney, are described under their appropriate headings.

Practically, the solid tumours of the kidney which come to be of clinical importance are all malignant in nature. Such tumours are characterized by the following special signs in addition to those enumerated above.

Hæmaturia is a frequent symptom, but, for the reasons given above, its presence must not be relied upon. If present it is usually intermittent and profuse. Albuminuria may also occur. The cells of a malignant growth may reach the urine, but they cannot with certainty be dis-

tinguished from the various epithelial cells which may also be present. Pain is experienced, and is sometimes very severe, occasionally shooting down in the direction of the ureter, often it is intermittent. The tumour itself may, however, be not even tender.

In most cases the general health rapidly suffers, but it is sometimes for a long period but slightly affected.

The tumours of clinical importance are generally primary, and therefore are limited to one side only. It must be mentioned that a malignant growth is sometimes so soft, and its consistence may be so much obscured by the interposition of intestine, that a sense of fluctuation is imparted, and the tumour may erroneously be diagnosed as of cystic nature.

Diagnosis.—Uncertainty in the diagnosis of tumours of the kidney will specially arise in connection with tumours of the liver, spleen and ovary, and accumulations of fæces in the colon.

When changes in the urine are present, little difficulty will, as a rule, be experienced; albeit, it must be remembered that hæmaturia need not necessarily be dependent upon a co-existing tumour in the abdomen.

In the absence of this indication, a tumour of the right kidney will be distinguished from one of the liver, by the possibility of passing the hand between the tumour and the liver, and possibly of feeling the edge of the liver, while often a line of resonance can be demonstrated between the tumour and the liver dulness. When the renal tumour is large, such separation from the liver is not to be made, but the position of the intestine in front of the tumour is a very safe indication of its renal origin, while, on the other hand, the presence of jaundice would strongly point to the liver as its seat.
